Bowlby's developmental pathways model has several implications for the design of studies of attachment and psychopathology. First, the most effective studies will include multiple levels of assessment. These assessments should include measures of attachment-related constructs at the individual level, of caregiving quality at the relationship level, and of distal and proximal stressors at the contextual level. Second, for prediction of psychopathology, it is important to assess the degree to which cumulative risk factors increase both the child's and the caregiver's exposure to stress. Third, longitudinal data are required to understand the dynamic relations among attachment-related aspects of personality, caregiving quality, and contextual risk. Although few existing studies comprehensively assess attachment, caregiving, and contextual risk, many of the more recent attachment studies that we have reviewed indicate that psychopathology is better understood when more than one level of assessment is incorporated in the study design.

Studies that follow the guidelines of a developmental pathways model will offer new opportunities to understand transactional processes that contribute to psychopathology. Three types of models appear to offer the most promise for hypothesis testing. Diathesis-stress models provide a specific hypothesis for how attachment organization and contextual stressors transact to produce psychopathology. More specifically, risk is increased when children with more extreme forms of insecure

attachment organization encounter high levels of stressors. Diathesis-stress models can be tested at the level of both the child's and the caregiver's attachment organization. In the case of caregivers, unresolved or hostile-helpless states of mind are thought to form a diathesis for deviant caregiving that should become most evident when caregivers encounter high levels of stress. A similar diathesis-stress hypothesis could also be tested for the emergence of caregiver psychopathology.

Mediation models may provide a way of distinguishing between attachment- and non-attachment-related risk for psychopathology. A large number of factors may increase risk for psychopathology, and many of these factors may elevate risk independent of attachment or caregiving processes. By testing the extent to which contextual or other risk factors are mediated through caregiving quality or attachment organization, more accurate estimates of the relative contribution of attachment processes to the emergence of psychopathology become possible.

Finally, longitudinal designs that incorporate multiple levels of assessment will provide a critical test of the early experience hypothesis. The most rigorous test of this hypothesis requires that assessment of attachment, caregiving, or contextual risk *early* in development accounts for variance in later outcomes above the variance accounted for by contemporaneous assessments of attachment, caregiving, and contextual risk. These longitudinal studies are the most demanding in terms of requiring multiple levels of measurement across developmental periods. It is these models, however, that most closely approximate a test of Bowlby's developmental pathways model.

Levels of Analysis and Attachment-Based Intervention

A common focus of most attachment interventions is to increase the child's sense of confidence in the availability and responsiveness of the caregiver (Levy & Orlans, 2003). However, the techniques of attachment interventions change dramatically with the developmental stage of the child. During infancy and early childhood, interventions must necessarily work at the caregiving level to improve the quality of care available to the child. As the caregiver increases his or her capacity to understand the child, accurately read his or her signals, and respond appropriately, the child is likely to gain confidence in the caregiver's availability and establish a foundation for increased self-confidence. A variety of techniques have been adopted to increase the caregiver's empathy and responsiveness to the child (Dozier,

Higley, Albus, & Nutter, 2002). These include providing parents with video-based feedback, increasing parents' capacity to observe, reflect, and verbalize their attributions about the child, and exploring the relevance of the parent's own caregiving history as it influences interactions with the child (Marvin, Cooper, Hoffman, & Powell, 2002).

As the child matures, interventions often maintain a dual focus on both the child's attachment and the caregiver's level of analysis. By middle childhood, the child's capacity for verbal communication and perspective taking transform the attachment relationship into a cooperative partnership (Bowlby, 1969/1982; Kobak & Duemmler, 1994). As a result, interventions may focus on both the child's and the caregiver's attributions and attachment strategies for maintaining the relationship. If successful, such interventions would contribute to reducing dysfunctional anger, increasing perspective taking, and reassuring the child of the availability and responsiveness of the caregiver. This focus on the attachment aspect of the relationship may be combined with other parenting interventions that focus more on the management and containment of disruptive child behavior (Cavell, 2000).

Both the caregiver's and the child's ability to engage in and benefit from intervention can be strongly influenced by the factors operating at the contextual level. Family-of-origin experiences and caregiver's state of mind with respect to attachment are both likely to influence the caregiver's style of forming a relationship with a therapist and the nature of the therapeutic relationship (Dozier, Lomax, Tyrell, & Lee, 2001). Contextual stressors associated with poverty limit caregivers' ability to utilize treatment and may be a common pathway through which contextual risk factors influence parenting behavior, perceptions of the child, and child behavior problems. Attachment-based interventions may improve a caregiver's ability to manage stress in multiple ways. First, interventions that reduce problematic child behavior may also reduce parental stressors. Second, attachment-based interventions may highlight the importance of using other adults as sources of support. Third, the ability of a caregiver or child to form a supportive relationship with the therapist may provide an important way of managing stress and benefiting from intervention.

CONCLUSIONS AND FUTURE DIRECTIONS 412

REFERENCES 413

The field of developmental psychopathology has undergone ontogenetic change in the past 2 decades, making numerous contributions (Cicchetti, 1993; Sroufe & Rutter, 1984). It has provided a unique perspective on both mental health and mental illness. It has challenged the very definition of psychopathology (see Cicchetti & Cohen, 1995; Sameroff, 2000). It has set the stage for the conceptualization of both risk and resilience for various disorders across the life span (see Cicchetti, 2004; Luthar & Cicchetti, 2000; Rutter & Sroufe, 2000) toward the goal of defining efforts at prevention, intervention, and treatment.

Critical to this endeavor has been a sensitivity to individual development over time, addressing why certain individuals' pathological conditions remain stable, whereas others are amenable to change. Moreover, as Sameroff (2000) cogently argues, the same symptoms may be caused by quite different processes at different developmental periods. In addition, for certain individuals suffering emotional, psychological, and behavioral disorders in childhood, there is little evidence of continuity into adulthood, whereas for others, symptoms persist. Understanding precisely why these differences exist represents a major challenge to the field.

Genetic studies have played a major role in enhancing our understanding of various pathologies (see review in Pennington, 2002). However, there has been a growing appreciation for the fact that the genetic throw of the dice is but one contributor to the various forms of psychopathol-

ogy. There has also been commendable attention to the fact that there is often no singular cause for a particular disorder; rather, there can be multiple pathways. For example, Cicchetti and Rogosch (1996, 2001) have argued that with regard to child maltreatment, there are multiple dimensions leading to subtypes of maltreatment symptomatology that involve a variety of neurological and psychological developmental processes. In our work, to take another example, we have examined the multiple pathways to depression among adolescents (Harter, 1999; from a methodological perspective, longitudinal studies have been critical in unraveling many of these issues; see Cicchetti, 2004).

Wearing my hat as a developmentalist, I am concerned, however, that the "development" in developmental psychopathology has not been given sufficient attention in terms of the contribution of development to our understanding of various forms of pathology. Development seems to be defined merely as time or age, leading to the importance of longitudinal research in this field. However, *age*, as a developmental predictor, has also been criticized as insufficient, as a crude marker for ontogenetic change (see Rutter & Sroufe, 2000). And well it should be, given the vast individual differences in normal and pathological development at any age. Historically, individual differences at any age level have been the bane of the developmentalist's existence. Moreover, our traditional developmental icons, Freud, Erikson, and Piaget, have fallen from theoretical grace because they did not sufficiently heed the warning that individual differences were damaging to their grand stage models.

Research funded by the W. T. Grant Foundation.

In our sophisticated efforts to right some of these theoretical wrongs, in our attempts to devise minitheories of a construct or a disorder, have we thrown out the developing baby with the bathwater? Have we turned our conceptual backs on the many developmental sequences that have been documented? Have we not respected the fact that contemporary investigators are quick to acknowledge that there are individual differences in the age at which developmental milestones are achieved? Therein lies the intrigue for those of us who continue to document interesting and compelling developmental sequences, while at the same time highlighting individual differences in the timing and manifestation of the particular behaviors that define any given normative developmental sequence. Might a basic appreciation for normative developmental sequences provide a backdrop for our understanding of deviations from those norms and thereby enhance our knowledge of the forms that pathology may take at different developmental levels?

I agree that an undue emphasis on the universals of developmental progressions (Rutter & Sroufe, 2000) may not be the beacon of light that illuminates our vision of developmental psychopathology, particularly if we adopt the very global developmental stage models of Freud, Erikson, and Piaget. Yet respect for the more circumscribed normative developmental sequences that have emerged in recent years, complemented by an acknowledgment of individual differences at any age, can provide insights into the causes of deviations from these normative paths. Moreover, it can prevent us from overinterpreting what are normative developmental “anomalies” (e.g., all-or-none thinking in the young child) as pathological.

In this chapter, therefore, I intend to put a little more “development” into our thinking about developmental psychopathology, particularly with regard to the *self-system*. Specifically, I focus on normative developmental changes in self-understanding and processes of self-evaluation across three periods of childhood (early, middle, and late childhood) and three periods of adolescence (early, middle, and late adolescence). For each of these six developmental periods, I first describe the normative developmental features of self-description and self-evaluation, drawing heavily on material presented in an earlier volume on the construction of the self (Harter, 1999). For each period, features include the salient content of the self, the structure or organization of self-constructs, the valence and accuracy of self-representations, the nature of social comparisons in forming self-judgments, and sensitivity to others as sources of information that may be relevant to self-representations.

Second, I describe the *normative developmental liabilities* that mark the emergence of each period or stage. The very fabric of development involves advances to new stages that may bring with them normative liabilities that should *not* be interpreted as pathological, liabilities that will dissipate as even more advanced developments and skills are acquired. There are numerous examples of where movement to a new stage of cognitive development leads to liabilities, given that the individual lacks “cognitive control” (see Fischer, 1980) over emerging new skills. Given that the self is not only a cognitive construction but a *social* construction (see Harter, 1999), crafted in the crucible of interactions with significant others, normative developmental manifestations of the self will necessarily be affected by socialization by parents and peers, to name the two key influences.

Third, I indicate how, at each developmental period, more serious forms of *psychopathology* may emerge given that self-development can be seriously derailed due to cognitive-developmental and socialization influences. These are to be distinguished from normative developmental liabilities in their severity and the extent to which they compromise the functioning of the child or adolescent at each period.

In addressing these three developmental components of the self-system, namely, normative developmental influences, liabilities associated with movement to a new developmental level, and more serious forms of psychopathology at each level, two causal factors, cognitive and social factors, are the primary focus on this chapter. I leave complex genetic interpretations in the hands of the many talented colleagues who have contributed to this subdomain of developmental psychology. However, where relevant, I touch generally on how genetic factors may indirectly affect self-representations and self-evaluations.

THE I-SELF AND THE ME-SELF

In addressing these themes, I occasionally draw on a distinction in the literature between the I-self and the Me-self. The majority of scholars who have devoted thoughtful attention to the self have come to a similar conclusion: Two distinct but intimately intertwined aspects of self can be meaningfully identified, self as subject (the I-self) and self as object (the Me-self). William James (1890, p. 197) introduced this distinction, defining the I-self as the actor or knower, whereas the Me-self is the object of one’s knowledge, “an empirical aggregate of things objectively known.” James also identified particular features or components of

both the I-self and the Me-self. Components of the I-self included (1) self-awareness, an appreciation for one's internal states, needs, thoughts, and emotions; (2) self-agency, the sense of the authorship of one's thoughts and actions; (3) self-continuity, the sense that one remains the same person over time; and (4) self-coherence, a stable sense of the self as a single, coherent, bounded entity. Components of the Me-self included the "material me," the "social me," and the "spiritual me," which in contemporary models translates into new domains of the self-concept as well as global self-esteem.

The distinction between the I-self and the Me-self has proved amazingly viable and appears as a recurrent theme in most theoretical treatments of the self. Others embellished on James's formulation and have employed somewhat different terminology, but the essence of the distinction has been retained. Dickstein (1977), for example, contrasted the "dynamic" self that possesses a sense of personal agency and control to the self as the object of one's knowledge and evaluation. Lewis and Brooks-Gunn (1979) initially defined this duality as the existential self and the categorical self. The task of the developing I-self, the self as subject, is to develop the realization that it is "existential" in that it exists as separate from others. The Me-self, namely, self as object, is referred to as "categorical" in that the developing child must construct categories by which to define himself or herself (e.g., age and gender labels). Wylie (1979, 1989) has summarized the essence of the distinctions that have been drawn by numerous theorists. The I-self is the active observer, whereas the Me-self is the observed, the product of the observing process when attention is focused on the self.

More recently, Lewis (1991, 1994) has adopted new terminology. He now refers to the I-self as the "machinery of the self," which represents basic biological, perceptual, and cognitive processes. Lewis describes the Me-self as the "idea of me," allowing the child to form representations of the self.

Actual cognitive representations of the self begin to emerge in rudimentary form in the second half of the 2nd year. Both the machinery of the self and the idea of me can undergo considerable change over the course of childhood and adolescence.

Until the past decade, major empirical attention had been devoted to the Me-self, to the study of the self as an object of one's knowledge and evaluation, as evidenced by the myriad studies on self-concept and self-esteem (see Harter, 1983; Wylie, 1979, 1989). More recently, the I-self, which James himself regarded as an elusive if not incorrigible con-

struct, has become more prominent in accounts of self-development. As we will come to appreciate in this chapter, both the structure and content of the Me-self at any given developmental level necessarily depend on the particular I-self capabilities, namely, those cognitive processes that define the knower. Thus, the cognitive-developmental changes in I-self processes will directly influence the nature of the self-theory that the child is constructing.

It should be noted that most scholars conceptualize the self as a theory that must be cognitively constructed. Those theorists in the tradition of adult personality and social psychology have suggested that the self theory should possess the characteristics of any formal theory, defined as a hypothetico-deductive system. Such a personal epistemology should, therefore, meet those criteria by which any good theory is evaluated, namely, the degree to which it is parsimonious, empirically valid, internally consistent, coherently organized, testable, and useful. From a developmental perspective, however, the self theories created by children cannot meet these criteria, given numerous cognitive limitations that have been identified in Piagetian (Piaget, 1960) and neo-Piagetian formulations (e.g., Case, 1992; Fischer, 1980); that is, the I-self in its role as constructor of the Me-self does not, in childhood, possess the capacities to create a hierarchically organized system of postulates that are internally consistent, coherently organized, testable, or empirically valid. In fact, it is not until late adolescence, if not early adulthood, that the abilities to construct a self-portrait meeting the criteria of a good formal theory potentially emerge. Therefore, in our developmental analysis of the self as a cognitive construction, it will be essential to examine how the changing characteristics of the I-self processes that define each developmental stage directly impact the Me-self, that is, the self-theory that is being constructed.

DEVELOPMENTAL DIFFERENCES IN SELF-REPRESENTATIONS DURING CHILDHOOD

In the following sections, the nature of self-representations and self-evaluations, at each of three periods of childhood—very early childhood, early to middle childhood, and middle to late childhood—are examined (see Table 11.1 for summary of cardinal features). For each period, there is a prototypical self-descriptive cameo (taken from Harter, 1999) that reflects the cardinal features of the content and structure of the self at that developmental level. Discussion fo-

TABLE 11.1 Normative Developmental Changes in Self-Representations during Childhood

Age Period	Salient Content	Structure/ Organization	Valence/ Accuracy	Nature of Comparisons	Sensitivity to Others
Very early childhood	Concrete, observable characteristics; simple taxonomic attributes in the form of abilities, activities, possessions, preferences	Isolated representations; lack of coherence, coordination; all-or-none thinking	Unrealistically positive; inability to distinguish real from ideal selves	No direct comparisons	Anticipation of adult reactions (praise, criticism); rudimentary appreciation of whether one is meeting others' external standards
Early to middle childhood	Elaborated taxonomic attributes; focus on specific competencies	Rudimentary links between representations; links typically opposites; all-or-none thinking	Typically positive inaccuracies persist	Temporal comparisons with self when younger; comparisons with age-mates to determine fairness	Recognition that others are evaluating the self; initial introjection of others' opinions; others' standards becoming self-guides in regulation of behavior
Middle to late childhood	Trait labels that focus on abilities and interpersonal characteristics; comparative assessments with peers; global evaluation of worth	Higher-order generalizations subsume several behaviors; ability to integrate opposing attributes	Both positive and negative evaluations; greater accuracy	Social comparison for purpose of self-evaluation	Internalization of others' opinions and standards, which come to function as self-guides

cues on an appreciation for these normative developmental changes that are critical as a backdrop against which one can judge whether a child's self-representations are age-appropriate. Against this backdrop, I examine the normative developmental liabilities for the construction of the self at this period. Finally, I examine what cognitive and social factors at each period will lead to distortions in self-development, deviations that can be considered more pathological in nature.

Very Early Childhood

Consistent with the theme of this chapter, we first address the very earliest verbal manifestations of the self. A cameo of normative self-descriptions will be followed by an analysis of the primary features at this age level, approximately 3 to 5. Normative *liabilities* are then discussed. Finally, pathological forms of self-development that go beyond normative liabilities are described.

Verbal Cameo of Normative Self-Representations and Self-Evaluations

I'm 3 years old and I live in a big house with my mother and father and my brother, Jason, and my sister, Lisa. I have blue eyes and a kitty that is orange and a television in my own room. I know all of my ABCs, listen: A, B, C, D, E, F, G, H, J, L, K, O, P, Q, R, X, Y, Z. I can run real fast. I like pizza and I have a nice teacher at preschool. I can count up to 100, want to hear me? I love my dog Skipper. I can climb to the top of the

jungle gym, I'm not scared! I'm never scared! I'm always happy. I have brown hair and I go to preschool. I'm really strong. I can lift this chair, watch me!

Such descriptions will typically be observed in 3- to 4-year-olds. Noteworthy in this descriptive cameo is the nature of the attributes selected to portray the self. Theory and evidence (see Fischer, 1980; Fischer & Canfield, 1986; S. Griffin, 1992; Harter, 1996, 1998; Higgins, 1991; Watson, 1990) indicate that the young child can construct only very concrete cognitive representations of observable features of the self (e.g., "I know my ABCs"; "I can count"; "I live in a big house"). Damon and Hart (1988) label these categorical identifications, reflecting the fact that the young child understands the self only as separate, taxonomic attributes that may be physical (e.g., "I have blue eyes"), active (e.g., "I can run real fast"; "I can climb to the top"), social (e.g., "I have a brother, Jason, and a sister, Lisa"), or psychological (e.g., "I'm always happy"). It is noteworthy that particular skills are touted (running, climbing) rather than generalizations about abilities, such as being athletic or good at sports. Moreover, often these behavioral descriptions will spill over into actual demonstrations of abilities ("I'm really strong. I can lift this chair, watch me!"), suggesting that these emerging self-representations are still very directly tied to behavior. From a cognitive-developmental perspective, they do not represent higher-order conceptual categories through which the self is defined. In addition to

concrete descriptions of behaviors, the young child defines the self in terms of preferences (e.g., "I like pizza"; "I love my dog Skipper") as well as possessions ("I have a kitty that is orange and a television in my own room"). Thus, as Rosenberg (1979) cogently observes, the young child acts as a demographer or radical behaviorist in that his or her self-descriptions are limited to characteristics that are potentially observable by others.

From the standpoint of organization, the self-representations of this period are highly differentiated or isolated from one another; that is, the young child is incapable of integrating these compartmentalized representations of self, and thus self-descriptive accounts appear quite disjointed. This lack of coherence is a general cognitive characteristic that pervades the young child's thinking across a variety of domains (Fischer, 1980). As Piaget (1960) himself observed, young children's thinking is transductive, in that they reason from particular to particular, in no logical order.

Neo-Piagetians have elaborated on these processes. For example, Case (1992) refers to this level as "interrelational," in that young children can forge rudimentary links in the form of discrete event-sequence structures that are defined in terms of physical dimensions, behavioral events, or habitual activities. However, they cannot coordinate two such structures (see also S. Griffin, 1992), in part because of working memory constraints that prevent young children from holding several features in mind simultaneously. Fischer's (1980) formulation is very similar. He labels these initial structures "single representations." Such structures are highly differentiated from one another, as the cognitive limitations at this stage render the child incapable of integrating single representations into a coherent self-portrait.

Moreover, self-evaluations during this period are likely to be unrealistically positive (e.g., "I know all of my ABCs" [which he or she doesn't!]) because young children have difficulty distinguishing between their desired and their actual competence, a confusion initially observed by both S. Freud (1952) and Piaget (1932). Thus, young children cannot yet formulate an ideal self-concept that is differentiated from a real self-concept. Rather, their descriptions represent a litany of talents that may transcend reality (Harter & Pike, 1984). For contemporary cognitive-developmentalists, such overstated virtuosity stems from another cognitive limitation of this period: the inability of young children to bring social comparison information to bear meaningfully on their perceived competencies (Frey & Ruble, 1990). The ability to use social comparison toward the goal of self-evaluation requires that the child be

able to relate one concept (his or her own performance) to another (someone else's performance), a skill that is not sufficiently developed in the young child. Thus, self-descriptions typically represent an overestimation of personal abilities. It is important to appreciate, however, that these apparent distortions are normative in that they reflect cognitive limitations rather than conscious efforts to deceive the listener.

Another manifestation of the self-structure of very young children is their inability to acknowledge that they can possess attributes of opposing valence, for example, good and bad, or nice and mean (Fischer, Hand, Watson, Van Parys, & Tucker, 1984). This all-or-none thinking can be observed in the cameo, in that all of the attributes appear to be positive. Young children's self-representations may also include emotion descriptors (e.g., "I'm always happy"). However, children at this age do not acknowledge that they can experience both positive and negative emotions, particularly at the same time. The majority will deny that they have negative emotions (e.g., "I'm never scared!") as salient features of their descriptive self-portrait. Other procedures reveal that they do have rudimentary concepts of such single negative emotions as mad, sad, and scared (see Bretherton & Beeghly, 1982; Dunn, 1988; Harter & Whitesell, 1989). However, a growing body of evidence now reveals that young children are incapable of appreciating the fact that they can experience seemingly opposing emotional reactions simultaneously (Carroll & Steward, 1984; Donaldson & Westerman, 1986; Gnepp, McKee, & Domanic, 1987; Harris, 1983; Harter & Buddin, 1987; Reissland, 1985; Selman, 1980). For Fischer and colleagues (e.g., Fischer & Ayoub, 1994), this dichotomous thinking represents the natural fractionation of the mind. Such "affecting splitting," as they term it, constitutes a normative form of dissociation that is the hallmark of very young children's thinking about both self and other.

It is important to appreciate the normative nature of this all-or-none thinking in understanding young children's reactions to everyday life events, particularly as they apply to the experience of negative affects. For example, one of our young interview participants described a situation in which he was being punished by his mother: "When I'm all bad my mother gets all mad, and when she's all mad, she gets a lot bigger!" In situations where the child is consumed with anger toward a parent or sibling, he or she may staunchly deny any feelings of affection or love (e.g., claiming only "I hate you!"). With regard to issues of loss, the young child may be pervasively sad over the death of a loved one, totally unable to acknowledge the positive emotions that

were undoubtedly also felt for the individual. Thus, at this particular developmental period, one would not want to conclude that such all-or-none reactions are abnormal or have clinical implications.

Cognitive limitations of this period extend to the inability of young children to create a concept of their overall worth as a person, namely, a representation of their global self-esteem or self-worth (Harter, 1990b). Such a self-representation requires a higher-order integration of domain-specific attributes that have first been differentiated. Young children do begin to describe themselves in terms of concrete cognitive abilities, physical abilities, how they behave, how they look, and friendships they have formed (Harter, 1990b). However, these domains are not clearly differentiated from one another, as revealed through factor-analytic procedures (Harter, 1998; Harter & Pike, 1984).

Behaviorally Presented Self-Esteem in Young Children. The fact that young children cannot cognitively or verbally formulate a general concept of their worth as a person does not mean they lack the experience of self-esteem. Rather, our findings (see Haltiwanger, 1989; Harter, 1990b, 1999) reveal that young children manifest self-esteem in their behavior. In examining the construct of behaviorally presented self-esteem, we first invoked the aid of nursery school and kindergarten teachers who had considerable experience with young children. We found that early childhood educators frequently make reference to children's self-esteem and that this is a very meaningful concept that distinguishes children from one another.

As a first step, we conducted open-ended interviews with about 20 teachers to generate an item pool from which we would eventually select those that best discriminate between high and low self-worth children. Teachers were asked to describe those behaviors that characterize the high self-esteem child, those that characterize the low self-esteem child, and those they felt did not allow them to discriminate between the two groups. Teachers had definite opinions about behaviors that were both relevant and irrelevant to this construct.

From these interviews we culled 84 behavioral descriptors, phrases that represent behaviors ranging from those that teachers felt did discriminate between high and low self-esteem children to those they felt were not relevant. We next employed a Q-sort procedure in which we asked a separate group of teachers to sort these 84 items into those that were most descriptive of the high self-esteem child at one end of the distribution, those that were most like the low self-esteem child at the other end, and those that were

neither like nor unlike the high or low self-esteem child in the middle. Thus, teachers performed a single sort based on their view of the prototype of both the high and low self-esteem child. Reliability analyses indicated very substantial agreement among teachers.

Behaviors That Discriminate between High and Low Self-Esteem Children. There were two primary categories of items that defined the high self-esteem child:

1. *Active displays of confidence, curiosity, initiative, and independence:* Examples include: trusts his or her own ideas, approaches challenge with confidence, initiates activities confidently, takes initiative, sets goals independently, is curious, explores and questions, is eager to try doing new things. Two other behaviors seemed to convey the more general manifestation of these attributes: describes self in positive terms and shows pride in his or her work.
2. *Adaptive reaction to change or stress:* Examples include: able to adjust to changes, comfortable with transitions, tolerates frustration and perseveres, able to handle criticism and teasing.

Similar categories describing the low self-esteem child representing the converse of these two sets of items emerged:

1. *Failure to display confidence, curiosity, initiative, independence:* Examples include: doesn't trust his or her own ideas, lacks confidence to initiate, lacks confidence to approach challenge, is not curious, does not explore, hangs back, watches only, withdraws and sits apart, describes self in negative terms, does not show pride in his or her work.
2. *Difficulty in reacting to change or stress:* Examples include: gives up easily when frustrated, reacts to stress with immature behavior, reacts inappropriately to accidents.

This content analysis is particularly illuminating given what it reveals about the nature of self-esteem as seen through the collective eyes of experienced teachers. They suggest two primary dimensions, one active and one reactive. The active dimension represents a style of approach rather than the display of skills per se. That is, the high self-esteem child manifests confidence in the world; the low self-esteem child avoids challenge, novelty, and exploration of the world. The reactive dimension involves the response of the child to change, frustration, or stress. The

high self-esteem child reacts more adaptively, whereas the low self-esteem child reacts with immature, inappropriate, or avoidant behaviors.

Of particular interest are the categories of behaviors that do *not* seem to discriminate between high and low self-esteem children according to teachers. Most noteworthy, if not striking, was the fact that *competence* per se is not a correlate of overall self-esteem in young children. It would appear that confidence, as a behavioral style, is not synonymous with competence, at least at this age level. This is illuminating because it suggests that the origins of a sense of confidence during early childhood do not necessarily reside in the display of skills, more objectively defined. During later childhood, the link between confidence in the self and one's level of competence apparently becomes stronger. This developmental pattern will include parental support, sensitivity, and contingent responsiveness, in general, as well as specific support for exploration, mastery, and curiosity that will promote a sense of confidence. As will become apparent in the antecedents of self-esteem that emerge in middle childhood, competence will become a much more critical factor. We would argue, in bridging these two developmental periods, that socialization practices that reward displays of confidence will lead the child to engage in behaviors that allow him or her to develop skills and competencies that will subsequently become a defining predictor of self-esteem.

Additional Functions of the Socializing Environment. In addition to the effect of parenting on behavioral manifestations of self-esteem, Higgins (1991), building on the efforts of Case (1985), Fischer (1980), and Selman (1980), focuses on how self-development during this period involves the interaction between the young child's cognitive capacities and the role of socializing agents. He provides evidence for the contention that at Case's stage of interrelational development and Fischer's stage of single representations, very young children can place themselves in the same category as the parent who shares their gender, which forms an initial basis for identification with that parent. Thus, the young boy can evaluate his overt behavior with regard to the question "Am I doing what Daddy is doing?" Attempts to match that behavior, in turn, will have implications for which attributes become incorporated into the young child's self-definition. Thus, these processes represent one way that socializing agents impact the self.

Higgins (1991) observes that at the interrelational stage, young children can also form structures allowing them to detect the fact that their behavior evokes a reaction in others, notably parents, which in turn causes psychological re-

actions in the self. These experiences shape the self to the extent that the young child chooses to engage in behaviors designed to please the parents. Stipek, Recchia, and McClintic (1992), in a laboratory study, have provided empirical evidence for this observation, demonstrating that slightly before the age of 2, children begin to anticipate adult reactions, seeking positive responses to their successes and attempting to avoid negative responses to failure. At this age, they also find that young children show a rudimentary appreciation for adult standards, for example, by turning away from adults and hunching their shoulders in the face of failures (see also Kagan, 1984, who reports similar distress reactions). For Mascolo and Fischer (1995), such reactions constitute rudimentary forms of shame. Shame at this period, like self-esteem, can only be *behaviorally* manifest. Children do not understand the concept at a verbal level (see Harter, 1999). Moreover, although young children are beginning to recognize that their behavior has an impact on others, their perspective-taking skills are extremely limited (see Harter, 1999; Selman, 1980). Thus, they are unable to incorporate others' opinions of the self into a realistic self-evaluation that can be verbalized.

The Role of Narrative in the Co-Construction of the Self. Another arena in which socialization agents in general and parental figures in particular impact children's self-development involves the role of narratives in promoting the young child's autobiographical memory, or a rudimentary story of the self. The infantile amnesia that one observes before the age of approximately 2 can be overcome only by learning from adults how to formulate their own memories as *narratives*. Initially, parents recount to the child stories about his or her past and present experiences. With increasing age and language facility, children come to take on a more active role in that parent and child co-construct the memory of a shared experience (Eisenberg, 1985; Hudson, 1990a, 1990b; Nelson, 1986, 1990, 1993; Rogoff, 1990; Snow, 1990). However for the young child, such narratives are still highly scaffolded by the parents, who reinforce aspects of experience that they feel are important to codify and remember (Fivush, Gray, & Fromhoff, 1987; Fivush & Hudson, 1990; Nelson, 1989). Through these interactions, an autobiographical account of the self is created. Of further interest are findings demonstrating individual differences in maternal styles of narrative construction (see Bretherton, 1993; Nelson, 1990, 1993). For example, Tessler (1991) has distinguished between an elaborative style (where mothers present an embellished narrative) and a pragmatic style (focusing more

on useful information). Elaborative mothers were more effective in establishing and eliciting memories with their young children.

For most developmental memory researchers, language is the critical acquisition allowing one to establish a personal narrative and to overcome infantile amnesia (Fivush & Hamond, 1990; Hudson, 1990a; Nelson, 1990; Pillemer & White, 1989). The mastery of language in general and of personal pronouns in particular enables young children to think and talk about the I-self and to expand their categorical knowledge of the Me-self (Bates, 1990; P. J. Miller, Potts, Fung, Hoogstra, & Mintz, 1990). Moreover, representations of the self in language are further facilitated by acquisition of the past tense, which occurs toward the second half of the 3rd year.

Howe (2003) and Howe and Courage (1993) argue, however, that the emergence of language is not sufficient to explain the demise of infantile amnesia and the emergence of an ability to create autobiographical memories. They note that self-knowledge is also required; that is, an appreciation for the self as an independent entity with actions, attributes, affects, and thoughts that are distinct from those of others is required for the development of autobiographical memory. Without the clear recognition of an independent I-self and Me-self, there can be no referent around which personally experienced events can be organized. Thus, for Howe and Courage, the emergence of the infant's sense of self is the cornerstone in the development of autobiographical memory that further shapes and solidifies one's self-definition.

Linguistic interactions with parents also impact the developing child's representation of self in semantic memory (Bowlby, 1969; Nelson, 1989, 1993; Snow, 1990). As Bowlby first noted, early semantic memory is conferred by caregivers. Parents convey considerable descriptive and evaluative information about the child, including labels to distinguish one from others (e.g., "You're a big boy"), evaluative descriptors of the self (e.g., "You are so smart"; "You're a good girl"), as well as rules and standards and the extent to which the child has met parental expectations (e.g., "Big boys don't cry"). Consistent with Cooley's (1902) model of the looking-glass self, children incorporate these labels and evaluations into their self-definition in the form of general trait knowledge (represented in semantic memory). Thus, the linguistic construction of the self is a highly interpersonal process, with caregivers making a major contribution to its representation in both autobiographical and semantic memory.

More recently, experts on infant memory development have suggested additional processes that may account for

childhood amnesia (see Hayne, 2004). Reviewing numerous studies of infant memory, Hayne concludes that there are three developmental processes that may add to our understanding of the infant's failure to retain autobiographical content. First, the large corpus of research first reveals that the *speed* with which infants encode information increases as a function of age. Second, the *retention* interval dramatically increases as a function of age during infancy. Third, the *flexibility* of memory retrieval improves during infancy, meaning that memories are not as bound by specific contextual or proximal cues, where changes in such cues can disrupt or preclude memory retrieval. Older infants have been found to gradually utilize more or different retrieval cues, allowing them to access memories in a wider range of situations. These newer explanations are not incompatible with earlier theories of the function of language and self-development but provide additional explanations for the phenomenon of infantile amnesia.

Normative Liabilities for Self-Development during Very Early Childhood

Clearly, infantile amnesia, given its several sources, including the lack of the development of the I-self and the Me-self around which memories can be organized, precludes a conscious sense of self for the infant and toddler. However, once very young children are able to verbally describe the self, their self-representations are limited to reflecting concrete descriptions of behaviors, abilities, emotions, possessions, and preferences that are potentially observable by others. These attributes are also highly differentiated or isolated from one another, leading to rather disjointed accounts, because at this age, young children lack the ability to integrate such characteristics. For some, this lack of a logical self-theory may be cause for concern, if not consternation. However, these features are normative in that the I-self processes, namely, the cognitive structures available at this developmental period, preclude a more logical rendering of the Me-self.

Self-representations are also likely to be unrealistically *positive* for several reasons. First, young children lack the cognitive ability to engage in social comparison for the purpose of self-evaluation. From a cognitive-developmental perspective, this skill, like many of the abilities that are unavailable to the preoperational child, as Piaget (1960) revealed, requires that one be able to hold two dimensions in mind simultaneously in order to compare them. Conservation tasks represent a prototype. Here, we apply this analysis to the inability to hold in mind an evaluation of one's own attributes while simultaneously

thinking about another's attributes, and then comparing them. This is beyond the abilities of the very young child.

Second, and for similar reasons, very young children are unable to distinguish between their *actual* self-attributes and their *ideal* self-attributes. This requires discriminating between the two, holding each in mind simultaneously, and comparing the two judgments, a cognitive ability that the very young child lacks. As a result, self-evaluations are unrealistically positive because the fusion of the two favors the ideal or desirable self-concept. Were one dealing with older children, one might interpret such a tendency to reflect socially desirable responding as the conscious distortion of one's self-evaluation to be favorable. Cognitive-developmental interpretations lead to a different conclusion: that the very young child's positive evaluations reflect cognitive limitations rather than a conscious attempt to deceive.

Third, young children lack the perspective ability to understand and therefore incorporate the perceived opinions of significant others toward the self (Harter, 1999; Selman, 1980). As will become evident in the discussion of middle childhood, the ability to appreciate others' evaluations of the self become powerful determinants of one's own sense of worth as a person emerges in middle childhood. At that developmental juncture, children typically believe and therefore incorporate the views of those socializing agents whose opinions they value, such as significant others who are nurturant and powerful (Harter, 1999). These processes are described later, in the context of Cooley's (1902) formulation of the looking-glass self that our own research has demonstrated to be alive and well, as an explanation for the antecedents of one's level of self-esteem beginning in middle childhood.

Cognitive limitations also lead to young children's inability to acknowledge that they can possess both positive and negative self-attributes. That is, the all-or-none, black-and-white thinking that is characteristic of the preoperational child extends to his or her conceptualizations of self. One must be one or the other. To the extent that the majority of socializing agents are relatively benevolent and supportive, the psychological scale will tip toward positive self-attributes. Thus, the young child will bask in the glow of overall virtuosity (albeit unrealistic).

The inability to possess a verbalizable concept of one's self-esteem can also be explained in terms of the cognitive limitations of this period. As will be documented, the subsequent ability to compare one's actual self-attributes with one's ideal self-attributes will become an important determinant of one's level of self-esteem. Perspective-taking abilities will also become critical given that the internal-

ization of the opinions of significant others becomes a powerful predictor of one's overall sense of personal worth. It was noted that *behavioral* manifestations of self-esteem do emerge during early childhood. However, it is an interesting empirical question as to whether the level of self-esteem so displayed parallels or predicts the concept of one's self-esteem that will emerge in middle childhood.

The description of the normative liabilities that impact conceptions and manifestations of the self during early childhood follows from normative cognitive limitations. One may question, however, the extent to which these actually reflect *psychological* liabilities. That is, many of the cognitive limitations of this period may serve as *protective* factors, to the extent that the very young child maintains very positive, albeit potentially unrealistic, perceptions of self. Positive self-views may serve as motivating factors, as emotional buffers, contributing to the young child's development. They may propel the child toward growth-building mastery attempts, instill a sense of confidence, and lead the child to rebuff perceptions of inadequacy, all of which may foster positive future development. From an evolutionary perspective, such liabilities may well represent very critical strengths for this developmental level. This issue will be revisited as we move up the ontogenetic ladder of representations and evaluations of the self.

Pathological Self-Processes and Outcomes in Early Childhood

A critical goal of this chapter is to distinguish between normative liabilities in the formation of the self and more pathological processes and outcomes at each developmental level. In very early childhood, what could serve to seriously derail normative self-development, leading to outcomes that would seriously compromise a very young child's psychological development? Typically, the causes of pathology involve an interaction between the child's level of cognitive development and chronic negative treatment at the hands of caregivers.

The Effects of Abuse. It should first be noted that it is not uncommon for children who experience severe and chronic sexual abuse to have also been subjected to other types of maltreatment, including verbal, physical, and emotional abuse (see Cicchetti, 2004; Harter, 1999; Rossman & Rosenberg, 1998). The normative penchant for very young children to engage in all-or-none thinking (e.g., all good versus all bad) will lead abused children, who have a rudimentary sense of parental attitudes toward the self, to view the Me-self as *all bad*. As noted earlier, the more typical pattern for children who are socialized by benevolent,

supportive parents is to view the self as all good. Abuse, as well as severe neglect (Bowlby, 1969) can, in turn, lead to early forms of depression, in which the very young child eventually becomes listless, unconnected to caregivers, and eventually emotionally numb.

Abuse or maltreatment can also affect I-self functions, for example, self-awareness, one of the basic functions of the I-self as originally described by James (1892). Briere (1992) points to a feature of abusive relationships that interferes with the victim's lack of awareness of self. The fact that the child must direct sustained attention to external threats draws energy and focus away from the developmental task of self-awareness. Thus, the hypervigilance to others' reactions, what Briere (1989) terms "other directness," interferes with the ability to attend to one's own needs, thoughts, and desires.

Research findings support these contentions. Cicchetti (1989) and colleagues (Cicchetti, Beeghly, Carlson, & Toth, 1990) found that maltreated children (ages 30 to 36 months) report less internal-state language, particularly negative internal feeling and physiological reactions, than do their nonmaltreated, securely attached counterparts (see also Beeghly & Cicchetti, 1994). Similar findings have been reported by Beeghly, Carlson, and Cicchetti (1986). Coster, Gersten, Beeghly, and Cicchetti (1989) have reported that maltreated toddlers use less descriptive speech, particularly about their own feelings and actions. Gralinsky, Feshbach, Powell, and Derrington (1993) have observed that older maltreated children report fewer descriptions of inner states and feelings than children with no known history of abuse. Thus, there is a growing body of evidence that the defensive processes that are mobilized by maltreated children interfere with one of the primary tasks of the I-self, namely, awareness of inner thoughts and feelings. Moreover, lack of self-awareness should also interfere with the ability to develop autobiographical memory.

Many attachment theorists contribute to our understanding of how maltreatment in early childhood can adversely influence self-development. There is considerable consensus that the vast majority of maltreated children form insecure attachments with their primary caregivers (Cicchetti et al., 1990; Crittenden & Ainsworth, 1989; Erickson, Egeland, & Pianta, 1989; Schneider-Rosen, Braunwald, Carlson, & Cicchetti, 1985; Westen, 1993). More recent findings have revealed that maltreated infants are more likely to develop disorganized-disoriented Type D attachment relationships (Barnett, Ganiban, & Cicchetti, 1999; Carlson, Cicchetti, & Barnett, 1989). Thus, the effects of early sexual and/or physical abuse, coupled with other forms of parental insensitivity, disrupt the attachment

bond, which in turn interferes with the development of positive working models of self and others. The foundation of attachment theory rests on the premise that if the caregiver has fairly consistently responded to the infant's needs and signals and has respected the infant's need for independent exploration of the environment, the child will develop an internal working model of the self as valued, competent, and self-reliant. Conversely, if the parent is insensitive to the infant's needs and signals, is inconsistent, and rejecting of the infant's bid for comfort and exploration, the child will develop an internal working model of the self as unworthy, ineffective, and incompetent (Ainsworth, 1979; Bowlby, 1973; Bretherton, 1991, 1993; Crittenden & Ainsworth, 1989; Sroufe & Fleeson, 1986). Clearly, the parental practices that have been associated with child abuse represent precisely the kind of treatment that would lead children to develop insecure attachments, as well as a concept of the self as unlovable and lacking in competence.

One critical function of parenting is to assist the child in creating a narrative of the self, the beginnings of one's life story, as it were, an autobiographical account that includes the perceptions of self and other (see Hudson, 1990a, 1990b; Nelson, 1986; Snow, 1990). Initially, these narratives are highly scaffolded by parents, who reinforce aspects of experience that they feel are important to codify and to remember or to forget (Fivush & Hudson, 1990; Hudson, 1990a; Nelson, 1986, 1990, 1993; Rogoff, 1990; Snow, 1990). More recent findings have revealed that the narratives of maltreated children contain more negative self-representations and more negative maternal representations compared to narratives of nonmaltreated children (Toth, Cicchetti, Macfie, & Emde, 1997; Toth, Cicchetti, Macfie, Maughan, & Vanmeenen, 2000). Moreover, such narratives show less coherence; that is, the self that is represented is less coherent or more fragmented (Crittenden, 1994; Macfie, Cicchetti, & Toth, 2001). These findings reveal greater signs of dissociative symptoms that reflect disruptions in the integration of memories and perceptions about the self. Thus, maltreatment at the hands of caregivers severely disrupts normative self-development that in turn leads to associated pathological symptoms, where it has been found that conflictual themes in young children's narratives predict externalizing problems in particular. Moreover, severe and chronic abuse has been associated with disorders such as Borderline Personality Disorder, where symptoms emerge later in development during adulthood (Putnum, 1993; Westen, 1993).

Language and False-Self Behavior. Language clearly promotes heightened levels of relatedness and

allows for the creation of a personal narrative. Stern (1985), however, alerts us to the liabilities of language. He argues that language can drive a wedge between two simultaneous forms of interpersonal experience, as it is lived and as it is verbally represented. The very capacity for objectifying the self through verbal representations allows one to transcend, and therefore potentially distort, one's immediate experience and to create a fantasized construction of the self. As noted in the previous section, there is the potential for incorporating the biases of caregivers' perspectives on the self because initially, adults dictate the content of narratives incorporated in autobiographical memory (Bowlby, 1980; Bretherton, 1987; Crittenden, 1994; Pipp, 1990). Children may receive subtle signals that certain episodes should not be retold or are best "forgotten" (Dunn, Brown, & Beardsall, 1991). Bretherton describes another manifestation, "defensive exclusion," in which negative information about the self or other is not incorporated because it is too psychologically threatening (see also Cassidy & Kobak, 1988). Wolf (1990) describes several mechanisms, such as deceit and fantasy, whereby the young child, as author of the self, can select, edit, or change the "facts" in the service of personal goals, hopes, or wishes (see also Dunn, 1988).

Such distortions may well contribute to the formation of a self that is perceived as inauthentic if one accepts the falsified version of experience. Winnicott's (1958) observations alert us to the fact that intrusive or overinvolved mothers, in their desire to comply with maternal demands and expectations, lead infants to present a false outer self that does not represent their own inner experiences. Moreover, such parents may reject the infant's "felt self," approving only of the falsely presented self (Crittenden, 1994). As Stern (1985) notes, the display of a false self incurs the risk of alienating oneself from those inner experiences that represent one's true self (see also Main & Solomon, 1990). Thus, linguistic abilities not only allow one to share experiences with others, but also to withhold them.

The Impoverished Self. As noted in the discussion of normative development during early childhood, an important function of parenting is to scaffold the child's construction of autobiographical memory in the form of a narrative of one's nascent life story. However, clinicians observe that maltreatment and neglect sow the seeds for children, beginning in early to middle childhood, to develop what we have come to call an "impoverished self," which has its roots in the early socialization practices of caregivers who fail to assist the child in the co-construction of a

positive, rich, and coherent self-narrative. In this regard, research (Tessler, 1991) has revealed individual differences among mothers: Some help to construct an embellished narrative, whereas others encourage a more restricted narrative that focuses on useful information, leading to fewer autobiographical memories. Clinical observations reveal that there is another group of parents who, because of their own dysfunction (e.g., depression) and parental inadequacies, do little to nothing in the way of co-constructing with the child a self-narrative. The seeds of an impoverished self, therefore, begin in early childhood and continue into middle childhood and beyond, if such children do not receive therapeutic intervention.

When these children come to the attention of family therapists, they lack a vocabulary to define the self, in that there is little in the way of autobiographical memory and descriptive or evaluative concepts about the self. An impoverished self represents one form of pathology, as the individual has few personal referents or self-concepts around which to organize present experiences. As a result, the behavior of such children will often appear to be disorganized. Moreover, to the extent that a richly defined self promotes motivational functions in terms of guides to regulate behavior and to set future goals, such children may appear aimless, with no clear pursuits. A clinical colleague of mine, Donna Marold (personal communication, August 1998), has astutely observed that these children do not have dreams for the future, whereas most children do have future aspirations. For example, the prototypical child in early to mid childhood indicates that he or she is going to be on a team someday. Marold notes, however, that the families of children with an impoverished self typically do not create or construct the type of narratives that provide a basis for autobiographical memory and a sense of self. Nor do such parents provide the type of personal labels or feedback that would lead to the development of semantic memory for self-attributes. Often, these are parents who do not take photographs of the children or the family, nor do they post the child's artwork or school papers on the refrigerator door. Marold has also observed that such parents do not have special rituals, such as cooking the child's favorite food or reading (and rereading) cherished bedtime stories.

What type of therapeutic interventions might be applicable in such cases, and how can they be guided by developmental theory and research? Therapists (myself included) have learned through trial and error that, with older children, one cannot simply try to instill, teach, or scaffold the self-structures appropriate for their age level, namely, trait labels that represent generalizations that integrate behav-

ioral or taxonomic self-attributes. With such children, there are few attributes to build on. Thus, one must begin at the beginning, using techniques that help the child create the missing narratives, the autobiographical memory, the self-labels. Marold has successfully employed a number of very basic techniques to achieve this goal, techniques that necessarily enlist the aid of parents. She suggests that the parent and child create a scrapbook in which whatever materials that might be available (the scant photograph, perhaps the school picture; a child's drawing; anything that may make a memory more salient) are collected and talked about. Where such materials are not available, Marold suggests cutting pictures out of magazines that represent the child's favorite possessions, activities, preferences—the very features that define the young child's sense of self. If there have been no routines that help to solidify the child's sense of self, Marold recommends that parents be counseled to establish routines, for example, establishing some family rituals (e.g., Friday night pizza) around a child's favorite food. Obviously, these techniques require collaboration with the parents and depend on their ability to recreate their child's past experiences, something that not all parents are equipped to do. In this regard, the therapist can serve as an important role model. From the standpoint of our developmental analysis, an impoverished self requires this type of support in early childhood.

Early to Middle Childhood

The verbal cameo of typical self-descriptions at the next stage of development, early to middle childhood, reveal both advances over the previous stage, as well as limitations, primarily due to cognitive-developmental level. After describing normative features, liabilities are addressed and contrasted to pathological features that may develop given child-rearing practices that compromise the self.

Verbal Cameo of Normative Self-Representations and Self-Evaluations

I have a lot of friends, in my neighborhood, at school, and at my church. I'm good at schoolwork, I know my words, and letters, and my numbers. I can run fast, and I can climb high, a lot higher than I could when I was little, and I can run faster, too. I can also throw a ball real far, I'm going to be on some kind of team when I am older. I can do lots of stuff real good. Lots! If you are good at things you can't be bad at things, at least not at the same time. I know some other kids who are bad at things but not me! (Well, maybe sometime later I could be just a very little bad, but not very often.) My

parents are real proud of me when I do good at things. It makes me really happy and excited when they watch me!

Such self-descriptions are typical of children ages 5 to 7. Some of the features of the previous stage persist: Self-representations are still typically very positive, and the child continues to overestimate his or her virtuosity. References to various competencies, for example, social skills, cognitive abilities, and athletic talents, are common self-descriptors. With regard to the advances of this age period, children begin to display a rudimentary ability to intercoordinate concepts that were previously compartmentalized (Case, 1985; Fischer, 1980). For example, they can form a category or representational set that combines a number of their competencies (e.g., good at running, jumping, schoolwork; having friends in the neighborhood, at school, and at church). However, all-or-none thinking persists. In Case's model and its application to the self (S. Griffin, 1992), this stage is labeled "unidimensional" thinking. At this age, such black-and-white thinking is supported by another new cognitive process: the child's ability to link or relate representational sets to one another, to "map" representations onto one another, to use Fischer's terminology. Of particular interest to self-development is one type of representational mapping that is extremely common in the thinking of young children: a link in the form of opposites. For example, in the domain of physical concepts, young children can oppose up and down, tall and short, thin and wide or fat, although they cannot yet meaningfully coordinate these representations.

Opposites can also be observed within the realm of the descriptions of self and others, where the child's ability to oppose good to bad is especially relevant. As observed earlier, the child develops a rudimentary concept of the self as good at a number of skills. Given that good is defined as the opposite of bad, this cognitive construction typically precludes the young child from being bad, at least at the same time. Thus, the oppositional mapping takes the necessary form of "I'm good and therefore I can't be bad." However, other people may be perceived as bad at these skills, as the cameo description reveals ("I know some other kids who are bad at things but not me!"). Children at this age may acknowledge that they could be bad at some earlier or later time ("Well, maybe sometime later I could be just a very little bad, but not very often"). However, the structure of such mappings typically leads the child to overdifferentiate favorable and unfavorable attributes, as demonstrated by findings revealing young children's inability to integrate attributes such as nice and mean (Fischer et al., 1984) or

smart and dumb (Harter, 1986a). Moreover, the mapping structure leads to the persistence of self-descriptions laden with virtuosity.

These principles also apply to children's understanding of their emotions, in that they cannot integrate emotions of opposing valence such as happy and sad (Harter & Buddin, 1987). There is an advance over the previous period, as children come to appreciate the fact that they can have two emotions of the same valence (e.g., "It makes me really happy and excited when [my parents] watch me"); that is, they can develop representational sets for feelings of the same valence, but there are separate emotion categories, one for positive emotions (happy, excited, proud) and one for negative emotions (sad, mad, scared). However, children at this stage cannot yet integrate the sets of positive and negative emotions, sets that are viewed as conceptual opposites and therefore incompatible. The inability to acknowledge that one can possess both favorable and unfavorable attributes, or that one can experience both positive and negative emotions, represents a cognitive liability that is a hallmark of this period of development. Unlike the previous period, now, due to greater cognitive and linguistic abilities, the child is able to verbally express his or her staunch conviction that one cannot possess both positive and negative characteristics at the same time. As one 5-year-old vehemently put it, "Nope, there is no way you could be smart and dumb at the same time. You only have one mind!"

The Role of the Socializing Environment. In addition to cognitive-developmental features affecting self-development, socializing agents also have an impact in interaction with cognitive acquisitions. Thus, children acquire an increasing cognitive appreciation for the perspective of others, which influences self-development. The relational processes of this level allow the child to realize that socializing agents have a particular viewpoint (not merely a reaction) toward them and their behavior (Higgins, 1991). As Selman (1980) observes, the improved perspective-taking skills at this age permit children to realize that others are actively evaluating the self (although children have not yet internalized these evaluations sufficiently to make independent judgments about their attributes). Nevertheless, as Higgins argues, the viewpoints of others begin to function as *self-guides* as the child comes to further identify with what he or she perceives socializing agents expect of the self. These self-guides function to aid the child in the regulation of his or her behavior.

One can recognize in these observations mechanisms similar to those identified by Bandura (1991) in his theory

of the development of self-regulation. Early in development, children's behavior is more externally controlled by reinforcement, punishment, direct instruction, and modeling. Gradually, children come to anticipate the reactions of others and to internalize the rules of behavior set forth by significant others. As these become more internalized, personal standards, the child's behavior comes more under the control of evaluative self-reactions (self-approval, self-sanctions), aiding in self-regulation and the selection of those behaviors that promote positive self-evaluation. The contribution of cognitive-developmental theory is to identify more clearly those cognitive structures making such developmental acquisitions possible. Moreover, the structures underlying such a shift represent rudimentary processes required for the incorporation of the evaluative opinions of significant others leading to self-evaluations. However, at this age level, cognitive-developmental limitations preclude the internalization of others' standards and opinions toward the self. Internalization, in which the child comes personally to "own" these standards and opinions, awaits further developmental advances.

As Higgins (1991) and Selman (1980), among others (see also Gesell & Ilg, 1946), have pointed out, although children at this age do become aware that others are critically evaluating their attributes, they lack the type of self-awareness that would allow them to be critical of their own behavior. In I-self/Me-self terminology, the child's I-self is aware that significant others are making judgments about the Me-self, yet the I-self cannot directly turn the evaluative beacon on the Me-self. These processes will emerge only when the child becomes capable of internalizing the evaluative judgments of others for the purpose of self-evaluation. As a result, children at this age period will show little interest in scrutinizing the self. As Anna Freud (1965) observed, young children do not naturally take themselves as the object of their own observation. They are much more likely to direct their inquisitiveness toward the outside world of events rather than the inner world of intrapsychic experiences.

With regard to other forms of interaction between cognitive-developmental level and the socializing environment, there are certain advances in the ability to utilize social comparison information, although there are also limitations. Frey and Ruble (1985, 1990) and Suls and Sanders (1982) provide evidence that at this stage, children first focus on temporal comparisons (how I am performing now, compared to when I was younger) and age norms, rather than individual difference comparisons with age-mates. As our prototypical subject tells us, "I can

climb a lot higher than when I was little and I can run faster, too.” Suls and Sanders observe that such temporal comparisons are particularly gratifying to young children given the rapid skill development at this age level. As a result, such comparisons contribute to the highly positive self-evaluations that typically persist at this age level. Evidence (reviewed in Ruble & Frey, 1991) now reveals that younger children do engage in certain forms of social comparison; however, it is directed toward different goals than for older children. For example, young children use such information to determine if they have received their fair share of rewards, rather than for purposes of self-evaluation. Moreover, findings reveal that young children show an interest in others’ performance to obtain information about the task demands that can facilitate their understanding of mastery goals and improve their learning (Frey & Ruble, 1985; Ruble & Dweck, 1995). However, they do not yet utilize such information to assess their competence, in large part due to the cognitive limitations of this period; thus, their evaluations continue to be unrealistic.

Normative Liabilities for Self-Development between Early to Middle Childhood

Many of the features of the previous stage persist, in that self-representations are typically very positive, and the child continues to overestimate his or her abilities. Moreover, the child at this period still lacks the ability to develop an overall concept of his or her worth as a person. With regard to advances, children do begin to display a rudimentary ability to intercoordinate self-concepts that were previously compartmentalized; for example, they can construct a representational set that combines a number of their competencies (e.g., good at running, jumping, school-work). However, all-or-none thinking persists due to a new cognitive process in which different valence attributes are verbally conceptualized as opposites (e.g., good versus bad, nice versus mean). Typically, this all-or-none structure leads to self-attributes that are all positive, and these beliefs are even more intractable than in the previous period given cognitive and linguistic advances that bring such beliefs into consciousness to the extent that the socializing environment supports such positivity.

Rudimentary processes allow the child to appreciate the fact that others are evaluating the self, although cognitive-developmental limitations preclude the child from internalizing these evaluations. Advances include the ability to make temporal comparisons to one’s past performance. Given the rapid skill development during these years, such comparisons contribute to the highly positive

self-evaluations that typically persist at this age level. The failure to use social comparison information for the purpose of self-evaluation, however, contributes to the persistence of unrealistically favorable self-attributes. As noted in describing the previous period, children at this stage are not consciously distorting their self-perceptions. Rather, they have not yet acquired the cognitive skills to develop more realistic self-perceptions.

Pathological Processes and Outcomes during Early to Middle Childhood

The potentials for pathological self-development that were identified for very early childhood exist for this subsequent period of development, particularly if the caregiving of socializing agents remains consistently negative. However, the effects may be amplified given that cognitive and linguistic acquisitions make such effects more evident, and given that the child is more able, with linguistic and cognitive advances, to better verbalize negative self-evaluations. In the case of chronic and severe abuse, the major coping strategy is *dissociation*, in which the individual attempts to cognitively split off the traumatic event from consciousness, to detach the self from the traumatic event (Herman, 1992; Putman, 1993; Terr, 1991). When such abuse occurs at this period of childhood, it conspires with the natural or normative penchant for cognitive dissociation, splitting, or fragmentation (Fischer & Ayoub, 1994). Moreover, the very construction of cognitive structures that consciously lead the child of this age to think in terms of opposites (one must be all good or all bad) leads to a painful awareness of that one must be *all bad*, that the self is totally flawed. This, in turn, can lead to compromising symptoms of depression.

Briere (1992), based on clinical cases, provides a complementary analysis of the sequential “logic” that governs the abused child’s attempt to make meaning of his or her experiences. Given maltreatment at the hands of a parent or family member, the child first surmises, “Either I am bad or my parents are bad.” However, the assumption of young children that parents or adult authority figures are always right leads to the conclusion that parental maltreatment must be due to the fact that they themselves were bad, that the act was their fault, and that therefore they deserve to be punished. When children are repeatedly assaulted, they come to conclude that they must be “very bad,” contributing to the sense of fundamental badness at their core.

From a cognitive-developmental perspective, the young child who is abused will readily blame the self (Herman, 1992; Piaget, 1932; Watson & Fischer, 1993; Westen, 1993); that is, given young children’s natural egocentrism,

they will take responsibility for events they did not cause or cannot control. Moreover, as Piaget demonstrated, young children focus on the deed (e.g., the abusive act) rather than on the intention (e.g., the motives of the perpetrator). As Herman points out, the child must construct some version of reality that justifies continued abuse and therefore inevitably concludes that his or her innate badness is the cause.

From an attachment theory perspective, the processes outlined in the preceding section will continue to negatively impact the self-development of children, to the extent that caregiving practices such as lack of sensitivity, neglect, noncontingent responsiveness, and other forms of maltreatment leading to insecure attachment styles continue. The impact of these practices may be amplified to the extent that the child can now *verbalize* his or her sense of inadequacy and lack of lovability. These now become etched in the child's conscious realization and expression of a negative sense of self. These should readily translate into experiences of profound sadness and lack of energy, symptoms of depression at this age level. Although no research to our knowledge has yet to examine our behaviorally presented self-esteem construct in depressed children, it can be predicted that there would be strong relationships between depression and behaviorally manifested low self-esteem at this age level.

The preceding section on very early childhood described the rudimentary antecedents of the impoverished self that reside in the fact that caregivers do not adequately support the child's construction of an autobiographical narrative of the sense of self. The effects of such lack of scaffolding should become more evident as children move into middle childhood and should be able to verbally express their autobiographical sense of self, a narrative of their past life story, with implications for the future. However, the failure to express dreams for the future, to positively describe one's capabilities, to express pride in one's accomplishments all reflect pathological distortions of self-development. These symptoms should represent serious red flags that require clinical intervention.

Middle to Late Childhood

There are dramatic differences between the emerging self-representations during middle to late childhood, ages 8 to 11, and those of the earlier childhood stages. The verbal cameo will illustrate these changes, followed by an analysis of why self-descriptions normatively change. As with any developmental advances, there are also accompanying lia-

bilities. A discussion of these liabilities is followed by how more extreme or pathological forms of self-development may be manifested.

Verbal Cameo of Normative Self-Representations and Self-Evaluations

I'm in fourth grade this year, and I'm pretty popular, at least with the girls. That's because I'm nice to people and helpful and can keep secrets. Mostly I am nice to my friends, although if I get in a bad mood I sometimes say something that can be a little mean. I try to control my temper, but when I don't, I'm ashamed of myself. I'm usually happy when I'm with my friends, but I get sad if there is no one to do things with. At school, I'm feeling pretty smart in certain subjects like language arts and social studies. I got As in these subjects on my last report card and was really proud of myself. But I'm feeling pretty dumb in math and science, especially when I see how well a lot of the other kids are doing. Even though I'm not doing well in those subjects, I still like myself as a person, because math and science just aren't that important to me. How I look and how popular I am are more important. I also like myself because I know my parents like me and so do other kids. That helps you like yourself.

Such self-descriptions are typically observed in children ages 8 to 11. In contrast to the more concrete self-representations of younger children, older children are much more likely to describe the self in such terms as "popular," "nice," "helpful," "mean," "smart," and "dumb." Children moving into late childhood continue to describe themselves in terms of their competencies (e.g., smart, dumb). However, self-attributes become increasingly interpersonal as relations with others, particularly peers, become an increasingly salient dimension of the self (see also Damon & Hart, 1988; Rosenberg, 1979).

From the standpoint of those emerging cognitive-developmental (I-self) processes, these attributes represent traits in the form of higher-order generalizations or concepts, based on the integration of more specific behavioral features of the self (see Fischer, 1980; Siegler, 1991). Thus, in the preceding cameo, the higher-order generalization that she is "smart" is based on the integration of scholastic success in both language arts and social studies. That she also feels "dumb" represents a higher-order construction based on her math and science performance. "Popular" also combines several behaviors, namely, being nice, being helpful, and keeping secrets.

The preceding developmental analysis focused primarily on advances in the ability to conceptualize self-attributes. However, the processes that emerge during this age period can also be applied to emotion concepts. Thus, the child de-

velops a representational system in which positive emotions (e.g., "I'm usually happy when I'm with my friends") are integrated with negative emotional representations (e.g., "I get sad if there is no one to do things with"), as a growing number of empirical studies reveal (Carroll & Steward, 1984; Donaldson & Westerman, 1986; Fischer, Shaver, & Carnochan, 1990; Gnepp et al., 1987; Harris, 1983; Harris, Olthof, & Meerum-Terwogt, 1981; Harter, 1986b; Harter & Buddin, 1987; Reissland, 1985; Selman, 1980).

This represents a major conceptual advance over the previous two age periods, during which young children deny that they can have emotions of opposing valences. Our own developmental findings (see Harter & Buddin, 1987) reveal that at this age, the simultaneous experience of positive and negative emotions can initially be brought to bear only on different targets. As one child subject observed, "I was sitting in school feeling worried about all of the responsibilities of a new pet but I was happy that I had gotten straight As on my report card." In Fischerian (Fischer, 1980) terms, the child at this level demonstrates a "shift of focus," directing the positive feeling to a positive target or event and then shifting to the experience of a negative feeling that is attached to a negative event. In middle childhood, the concept that the very same target can simultaneously provoke both a positive and a negative emotion is not yet cognitively accessible. However, by late childhood, positive and negative emotions can be brought to bear on one target given the emergence of representational systems that better allow the child to integrate emotion concepts that were previously differentiated. Sample responses from our empirical documentation of this progression (Harter & Buddin, 1987) were as follows: "I was happy that I got a present but mad that it wasn't what I wanted"; "If a stranger offered you some candy, you would be eager for the candy but worried about whether it was okay."

Social Processes. A more balanced view of self, in which positive as well as negative attributes of the self are acknowledged, is also fostered by social comparison. As our prototypical subject reports, "I'm feeling pretty dumb in math and science, especially when I see how well a lot of the other kids are doing." A number of studies conducted in the 1970s and early 1980s presented evidence revealing that it is not until middle childhood that the child can apply comparative assessments with peers in the service of self-evaluation. From a cognitive-developmental perspective, the ability to use social comparison information toward the goal of self-evaluation requires that the child have the ability to relate one concept to another si-

multaneously, an ability not sufficiently developed at younger ages. In addition to the contribution of advances in cognitive development (see also Moretti & Higgins, 1990), age stratification in school stimulates greater attention to individual differences between age-mates (Higgins & Bargh, 1987; Mack, 1983). More recent findings reveal that the primary motive for children in this age period to utilize social comparison is for personal competence assessment.

The ability to utilize social comparison information for the purpose of self-evaluation is founded on cognitive-developmental advances, namely, the ability to simultaneously compare representations of self and others. However, it is also supported by the socializing environment. For example, evidence reveals that as children move up the academic ladder, teachers make increasing use of social comparison information (J. P. Eccles & Midgley, 1989; J. S. Eccles, Midgley, & Adler, 1984) and that students are well aware of these educational practices (Harter, 1996). Moreover, parents may contribute to the increasing salience of social comparison, to the extent that they make comparative assessments of how their child is performing relative to siblings, friends, or classmates.

A Developmental Acquisition Sequence of the Understanding of Pride and Shame. In the cameo self-description, the child not only describes the self in terms of basic emotions such as happy and sad, but also makes reference to self-affects or self-conscious emotions such as pride and shame ("I got As in [language arts and social studies] on my last report card and was really proud of myself"; "I try to control my temper, but when I don't, I'm ashamed of myself"). It is not until this age level that self-affects appear in the child's repertoire of self-representations.

Cooley's (1902) formulation spoke to this issue in that the development of the self includes not only the internalization of the opinions of significant others but the incorporation of their affective reactions to the self, specifically, pride and shame, leading ultimately to the ability to feel proud of oneself as well as ashamed of oneself. Moreover, Cooley set the stage for a developmental analysis of how these emotions might emerge. Although pride and shame could clearly be experienced by adults in the absence of others, Cooley noted that "the thing that moves us to pride and shame is not the merely mechanical reflection of ourselves, but an imputed sentiment, the imagined effect of this reflection upon another's mind" (p. 153). Cooley was clear that this sentiment is social in nature, based on social custom and opinion, although it becomes somewhat removed from these sources

through an implied internalization process. Cooley writes that the adult is

not immediately dependent upon what others think; he has worked over his reflected self in his mind until it is a steadfast portion of his thought, an idea and conviction apart, in some measure, from its external origin. Hence this sentiment requires time for its development and flourishes in mature age rather than in the open and growing period of youth. (p. 199)

Cooley's views on the internalization of others' opinions about the self paved the way for a more developmental perspective on how the attitudes of others are incorporated into the self.

In our own work (Harter, 1999), we have provided documentation for a 4-stage developmental sequence governing the development of the conceptual *understanding* of pride and shame. Younger children may manifest or display the emotions of pride and shame through facial expressions and bodily posture (see review by Stipek, 1995). However, it is not until middle to late childhood that they can verbalize the capacity to be proud or ashamed of *one-self* and that such self-affects become part of their self-definition. In particular, we were interested in the substages that appeared to be precursors of the child's emerging ability to appreciate the fact that one could be proud or ashamed of the self in the absence of any observation by others.

Focusing on the socialization component of both pride and shame, we devised a procedure that would be sensitive to the role of the observing parent; that is, we sought to determine whether parents were required to "support" the reported experience of pride and shame (Harter, 1999). Toward this end, we designed two sets of vignettes. To assess shame, we constructed a pictorial vignette with several frames and a brief story line to accompany the pictures. The story concerned a situation in which the parents have forbidden the child to take any money from a very large jar of coins in the parents' bedroom. However, the child transgresses and takes a few coins. There are two separate story sequences. In one sequence, no one observes the act, and no one ever finds out (an outcome we attempted to ensure by describing the money jar as very large, whereas the child took only a few coins). In the second sequence, the parent catches the child in the act. The primary dependent measures included the subject's description of the emotions that the story child would feel in the first sequence (where the act is not detected) and a description of the emotions that both child and parent would

feel in the second situation (where the parent catches the child in the act).

To assess an understanding of pride, we selected a gymnastic feat as the demonstration of competence. In the first sequence, the child goes to the playground on a Saturday when no one else is there and tries out a flip on the bars, one that he or she has been working on at school. The child attempts this maneuver, which he or she has never been able to perform successfully before, and does it really well. In the first sequence, the child leaves the bars knowing that he or she was the only one at the playground and thus no one else observed the flip. The child is then asked what feeling he or she would have at that time. In the second pride sequence, the parent accompanies the child to the playground and observes the child successfully performing the flip for the first time. The child is asked how he or she would feel, as well as how the observing parent would feel having watched the child doing the flip. In all conditions, pictorial aids in the form of photographs of facial expressions of a series of emotions by a child, for the first sequence, and by a child and a parent, for the second sequence, are presented to the children to facilitate their identification of relevant affects.

The results for both pride and shame revealed a highly age-related, parallel, 4-stage sequence that is interpretable within our socialization framework. Moreover, the stages that emerged are consistent with Selman's (1980) developmental model of self-awareness, in which children gradually begin to observe and critically evaluate the self. At our first level, ages 4 to 5, there is no mention of either pride or shame on the part of the story child or the parent in either sequence, whether the child is observed or not observed. Participants give very clear responses about their potential emotional reactions to these situations, reactions that are quite telling. In the transgression situation where the story child is not observed by the parents, participants report that the child character (with whom they are encouraged to identify) would feel scared or worried about the possibility of detection. When caught by the parent, he or she feels extremely scared or worried about the likelihood of punishment. However, there is no acknowledgment of pride or shame.

In the pride sequences of stories, these youngest subjects report that they would feel happy, glad, and excited in the situation where their gymnastic feat is not observed by the parent. In the story where the parent witnesses their performance, they report that both they and the parent would feel happy, glad, and excited; that is, there is no mention of pride, on the part of either the parent or the story

child. Thus, children at this first level are aware that their parents have reactions to their behavior. However, consistent with Selman's (1980) first level of self-awareness and with Higgins's (1991) analysis, the child is not yet aware that others are evaluating the self, nor can the I-self critically evaluate or affectively react to the Me-self.

Our second level at ages 5 to 6 represents a very interesting transition period. Children now demonstrate their first use of the terms "ashamed" and "proud." However, their usage is restricted to reactions of the parents. Thus, the parental response to the child's transgression is to be ashamed of the child. However, the child does not yet acknowledge that he or she is ashamed of the self. Rather, the child is still scared or worried about the parents' reaction. Similarly, in the case of the gymnastic feat, the subjects describe how the parent is proud of the child. However, the child is not yet proud of the self; rather, he or she is excited, happy, glad.

This level parallels Selman's (1980) second stage of self-awareness and is consistent with Higgins's (1991) analysis; that is, the child's I-self is aware that others are observing and evaluating and affectively reacting to his or her Me-self ("I observe you evaluating and being proud or ashamed of me"). This second level, therefore, provides the necessary building blocks for the emergence of the looking-glass self (Cooley, 1902), in which one comes to internalize the attitudes, opinions, and affective sentiments of significant others toward the self; that is, children must first be sensitive to the fact that they are being evaluated in order to direct their attention to the specific content of others' approval, criticism, and emotional reactions.

At our third level, children between the ages of 6 and 7 acknowledge that shame and pride can be directed by the self, toward the self. Thus, in the situation where the act has been observed, not only will parents be ashamed or proud of the child, but children report that they, too, will feel ashamed or proud of themselves, seemingly in response to the parental reaction. However, what also places children at this level is the fact that they do not report any feelings of shame or pride in the story sequence specifying the absence of parental observation. This seems to be another critical transitional level in our socialization sequence: The act must be observed in the case of both a transgression (in order to experience shame) and the demonstration of competence (in order to experience pride). In the absence of parental observation, no such potential self-affects are acknowledged. This level parallels Selman's (1980) third stage of self-awareness, when the child begins to incorpo-

rate the observations of others into his or her own self-perceptions, such that he or she can directly evaluate the self. Thus, the I-self can now adopt an attitude toward the Me-self that parallels the attitude of significant others, although these self-attitudes and self-affects must still be scaffolded by others.

The hallmark of the fourth level, beginning at ages 7 to 8, is that in the absence of parental observation, children spontaneously acknowledge that the story children will feel ashamed of themselves or proud of themselves. (It should be noted that the stories in which the child was not observed were always presented first, so that any response of shame or pride on the part of the child was not simply a generalization from the sequence in which he or she was observed.) Therefore, at this level, children appear to have internalized the standards by which shame and pride can be experienced in the absence of direct parental observation. Interestingly, the large majority of children at this level do not merely report the emotions of shame and pride, but specifically indicate "I would feel ashamed (or proud) of myself." Thus, they appear to be at the stage where these emotions do function as self-affects in the sense that one is truly ashamed or proud of the self. This final level in our sequence is consistent with Selman's (1980) fourth stage, in which the I-self can now observe and critically evaluate the Me-self in the absence of the direct presence or reactions of significant others.

In summary, this sequence not only reveals the gradual nature of the normative developmental emergence of self-affects, but also suggests that the critical, underlying processes involve parental socialization. Thus, we have inferred that children must first experience others as models who are proud or ashamed of them in order to internalize these functions themselves. Even when they first develop the ability to acknowledge that they are proud or ashamed of themselves, children still need the scaffolding of parental surveillance or observation. The final stage in the internalization process occurs when these self-affects are experienced in the absence of observations by others, when the I-self can be directly ashamed of the Me-self, when one is all by oneself.

Possible Genetic Influences on Self-Esteem. The discussion thus far has focused on psychological mechanisms that account for a child's level of self-esteem, describing the contribution of cognitive-developmental and social determinants. For many years, these have been the prevailing theories. Recently, neurological and genetic models have come to the fore. The 1990s were declared the

Decade of the Brain, and it became obvious that our splintered subfields needed to be integrated if we were truly to understand development and human behavior. How might such a genetic perspective be applied to differences in levels of self-esteem in children? I am not a geneticist, nor have I done such work. However, other investigators present findings that suggest (statistical) heritability of self-esteem. The empirical findings cannot be disputed (see McGuire et al., 1999; Neiss, Sedikides, & Stevenson, 2002).

Does this mean that there is a “self-esteem” gene? I think not. Might there be heritability? Yes. What might be a thoughtful explanation? We know a great deal about heritability from many compelling studies of intelligence, temperament, athleticism, and creativity, to name but a few characteristics. There are also considerable data demonstrating the heritability of conditions such as various learning disabilities, Autism, and Attention-Deficit/Hyperactivity Disorder (ADHD; see Pennington, 2002). These studies can be linked to the issue of the heritability of self-esteem. That is, if the genetic throw of the dice causes a child to be intellectually competent, athletically competent, or attractive by current societal standards, and if parents, peers, and others reward those characteristics and also reinforce their importance, then according to James (1890, 1892) and our own findings, this child is on the path to high self-esteem. If children are genetically blessed with a sociable temperament and are rewarded for their sociability by parents, teachers, and peers, then, from a looking-glass self perspective, they will receive positive feedback that will enhance their self-esteem. Thus, I see the constructs that I have identified to be mediators of self-esteem, impacted by genetics. But I do not think it is reasonable to conclude that there is a direct connection between genes and self-esteem.

Normative Liabilities for Self-Development during Middle to Late Childhood

A cardinal thesis of this chapter is that cognitive advances, that is, movement to new cognitive-developmental levels, paradoxically bring about normative liabilities for the self-system, as implied in the discussion of normative self-descriptions. In this section, the liabilities are highlighted. The ability to be able to construct a global perception of one’s worth as a person represents a major developmental acquisition, a milestone, in terms of a shift from mere domain-specific self-perceptions to an integrated sense of one’s overall self-esteem. However, other cognitive-developmental acquisitions can serve to lower the valence of this global perception of self, leading to lowered self-

esteem. Findings clearly reveal (see Harter, 1999) that beginning in middle childhood, self-perceptions become more negative, normatively, compared to the very positive self-perceptions of the majority of young children. As noted earlier, the emergence of three cognitive skills are noteworthy in this regard: (1) the ability to use social comparison for the purpose of self-evaluation, (2) the ability to differentiate real from ideal self-perceptions, and (3) increases in social perspective-taking skills.

The ability to employ social comparison for the purpose of self-evaluation (see Maccoby, 1980; Moretti & Higgins, 1990; Ruble & Frey, 1991) leads many, with the exception of the most competent or adequate in any given domain, to fall short in their self-evaluations. If one therefore judges oneself deficient compared to others in domains that are deemed important to the self (typically defined by the importance hierarchies of significance to others), then global self-esteem will be eroded. Thus, the very ability and penchant, supported by the culture (e.g., family, peers, schools, the media), to compare oneself with others makes one vulnerable in valued domains (e.g., appearance, popularity, scholastic competence, athletic performance, and behavioral conduct).

A second newfound cognitive ability to emerge in middle to late childhood involves the capacity to make the distinction between one’s real and one’s ideal self. From a Jamesian perspective, this skill involves the ability to distinguish between one’s actual competencies or adequacies and those to which one aspires, namely, those that one deems important. The cognitive realization that one is not meeting one’s expectations (an ability that young children do not possess) will necessarily lower one’s overall level of self-esteem, as James’s (1890) formulation accurately predicts. Moreover, findings (see Glick & Zigler, 1985; Leahy & Shirk, 1985; Oosterwegel & Oppenheimer, 1993) reveal that the real-ideal discrepancy tends to increase with development. Two causes of such an increase can be identified. First, as noted earlier, social comparison processes lead older children to lower the valence of their self-perceptions, viewing themselves less positively. Second, given increasing perspective-taking skills, children are becoming increasingly cognizant of the standards and ideals that socializing agents hold for their behavior. Moreover, parents, teachers, and peers may normatively raise the bar in terms of their expectations, leading to higher self-ideals in an attempt to please significant others.

Increased perspective-taking skills can also *directly* impact self-perceptions, leading them to be more realistic. Protected by limitations in the ability to divine what others

truly think of the self, younger children can maintain very positive self-perceptions. The developing ability to more accurately assess the opinions that others hold about one's characteristics, coupled with increasing concern about the importance of the views of others toward the self, normatively lead many older children to realistically lower their self-evaluations.

We can ask whether these processes that lead to more realistic self-evaluations in fact represent liabilities. Many have argued (see review in Harter, 1999) that realistic self-evaluations are more adaptive beginning in middle to late childhood. Thus, the initial liabilities, in terms of psychological blows to one's self-image, may be temporary as the child seeks to realistically readjust his or her self-perceptions and pursue more adaptive paths of development that are consistent with his or her actual attributes.

Pathological Self-Processes and Outcomes in Middle to Late Childhood

Pathological outcomes will typically result from an interaction between a child's cognitive-developmental level and the behavior of socializing agents, where parental figures are the most immediate influences. During middle to late childhood, when children add to their repertoire of domain-specific self-evaluations the more global concept of self-esteem, both types of self-representations are vulnerable to the influence of caregivers. As described in the sections on normative processes, benevolent socializing agents readily provide the nurturance, approval, and support that is mirrored in self-evaluations that are positive. Approval, in the form of the reflected appraisals of others, is, therefore, internalized as acceptance of self. However, in the search for their image in the social mirror, children may well gaze through a glass darkly. Caregivers lacking in responsiveness, nurturance, encouragement, and approval, as well as socializing agents who are rejecting, punitive, or neglectful, will cause their children to develop tarnished images of self. Attachment theorists echo this theme (see Bretherton, 1991; Sroufe, 1990). They observe that children who experience parents as emotionally available, loving, and supportive of their mastery efforts will construct a working model of the self as lovable and competent. In contrast, children who experience attachment figures as rejecting or emotionally unavailable and nonsupportive will construct a working model of the self as unlovable, incompetent, and generally unworthy.

In the extreme, children subjected to severe and chronic abuse create images of the self that are despicable (Briere, 1992; Fischer & Ayoub, 1994; Herman, 1992; McCann &

Pearlman, 1992; Terr, 1990; van der Kolk, 1987; Westen, 1993; Wolfe, 1989). More than constructing negative self-perceptions, they view the self as fundamentally flawed. Often, excessively high and unrealistic parental standards that are unattainable contribute to these negative views of self. Thus, the Me-self, both at the level of domain-specific self-perceptions and one's sense of global self-esteem, may be irrevocably damaged.

A central tenet of neo-Piagetian models is that movement to a new stage of development can be fostered by socializing agents or, alternatively, can be delayed if such environmental support is not forthcoming. One can imagine scenarios in which there would be little environmental support for the integration of positive and negative attributes or positive and negative emotions. For example, in situations where children are chronically and severely abused, family members typically reinforce negative evaluations of the child that are then incorporated into the self-portrait (Briere, 1992; Fischer & Ayoub, 1994; Harter, 1998; Herman, 1992; Terr, 1990; Westen, 1993). As a result, there may be little scaffolding for the kind of self-structure that would allow the child to develop as well as integrate both positive and negative self-evaluations. Moreover, negative self-evaluations that become automatized (Siegler, 1991) will be even more resistant to change.

Thus, to the extent that there is little or no support for the normative integration of positive and negative attributes, children will not advance cognitively. If the majority of feedback from socializing agents is negative, then children in this age range (8 to 12) may remain at the previous level of all-or-none thinking, viewing their behavior as overwhelmingly negative.

A considerable body of research (see review in Harter, 1999) reveals that there is a very robust relationship between negative self-perceptions, including low self-esteem, and depression. Depressive symptoms include lack of energy, profound sadness in the form of depressed affect, and hopelessness. Depression, in turn, is highly predictive of suicidal ideation and suicidal behavior. Thus, caregiving practices resulting in very negative perceptions of the self put children at risk for serious forms of depressive pathology.

Moreover, not only do the evaluations of significant others result in representations of self, but they provoke powerful self-affects in the form of pride and shame (see Harter, 1999). Thus, children who receive praise and support for their efforts will develop a sense of pride in their accomplishments. However, children who are chronically

criticized for their performance will develop a sense of shame that can be psychologically crippling. At this level of development, the child has internalized shame as a self-affect, carrying the burden of being ashamed of the self.

For children who have experienced severe and chronic abuse, these processes are exacerbated and extend to guilt and shame. Closely linked to abuse victims' perceptions of low self-esteem, self-blame, and a sense of inner badness are emotional reactions of guilt and shame (see Briere, 1992; Herman, 1992; Kendall-Tackett, Williams, & Finkelhor, 1993; McCann & Pearlman, 1992; Terr, 1990; Westen, 1993; Wolfe, 1989). Normatively, such self-affects are intimately related to evaluative self-perceptions, both of which result from the internalization of the opinions of significant others (Cooley, 1902; Harter, 1998). Thus, the blame, stigmatization, condemnation, and ostracism that parents, family, and society express toward the abuse victim not only are incorporated into attributions of self-blame but also result in powerful negative affects directed toward the self. The sexual abuse victim is made to feel humiliated for his or her role in shameful acts. Guilt and shame are also fueled by the perception that one's badness led to the abuse, rather than the abuse being the cause of one's negative self-views.

In addition to the incorporation of the opinions of significant others, children come to internalize the standards and values of those who are important to them, including the values of the larger society. Perceptions of one's physical attractiveness, in relation to the importance that is attached to meeting cultural standards of appearance, contribute heavily to one's overall sense of worth as a person (see Harter, 1993, 1999). Those who feel they have attained the requisite physical attributes will experience relatively high levels of self-esteem. Conversely, those who feel that they fall short of the punishing standards of appearance that represent the cultural ideal will suffer from low self-esteem and depression. A related liability can be observed in the eating-disordered behavior of females in particular, many of whom display symptoms (e.g., associated with anorexia) that are life-threatening (Harter, 1999). Our own recent findings (Kiang & Harter, 2004) provide support for a model in which endorsement of the societal standards of appearance leads to low self-esteem, which in turn predicts both depression and eating-disordered behavior. Finally, genetic factors that may lead to physical characteristics that do not meet cultural standards of attractiveness will also contribute to this pattern and may be particularly resistant to change.

DEVELOPMENTAL DIFFERENCES IN SELF-REPRESENTATIONS DURING ADOLESCENCE

The period of adolescence represents a dramatic developmental transition, given pubertal and related physical changes, cognitive-developmental advances, and changing social expectations. With regard to cognitive-developmental acquisitions, adolescents develop the ability to think abstractly (Case, 1985; Fischer, 1980; Flavell, 1985; Harter, 1983; Higgins, 1991). From a Piagetian (Piaget, 1960) perspective, the capacity to form abstractions emerges with the stage of formal operations in early adolescence. These newfound acquisitions, according to Piaget, should equip the adolescent with the hypothetico-deductive skills to create a formal theory. This observation is critical to the topic of self-development, given the claims of many (e.g., Epstein, 1973, 1981, 1991; Greenwald, 1980; Kelly, 1955; Markus, 1980; Sarbin, 1962) that the self is a personal epistemology, a cognitive construction; that is, a theory that should possess the characteristics of any formal theory. Therefore, a self-theory should meet those criteria by which any good theory is evaluated, criteria that include the degree to which it is parsimonious, empirically valid, internally consistent, coherently organized, testable, and useful. From a Piagetian perspective, entry into the period of formal operations should make the construction of such a theory possible, be it a theory about elements in the world or a theory about the self.

However, as will become apparent, self-representations during early and middle adolescence fall far short of these criteria. The self-structure of these periods is not coherently organized, nor are the postulates of the self-portrait internally consistent. Moreover, many self-attributes fail to be subjected to tests of empirical validity; as a result, they can be extremely unrealistic. Nor are self-representations particularly parsimonious. Thus, the Piagetian framework fails to provide an adequate explanation for the dramatic developmental changes in the self-structure that can be observed across the substages of adolescence. Rather, as in our analysis of how self-representations change during childhood, a neo-Piagetian approach is needed to understand how changes in cognitive-developmental I-self processes result in very different Me-self organization and content at each of three age levels: early adolescence, middle adolescence, and late adolescence.

Early Adolescence

As in our examination of self-development during childhood, for each age level we first describe the normative de-

TABLE 11.2 Normative Developmental Changes in Self-Representations during Adolescence

Age Period	Salient Content	Structure/ Organization	Valence/ Accuracy	Nature of Comparisons	Sensitivity to Others
Early adolescence	Social skills, attributes that influence interactions with others or one's social appeal; differentiation of attributes according to roles	Intercoordination of trait labels into single abstractions; abstractions compartmentalized; all-or-none thinking; opposites; don't detect, integrate opposing abstractions	Positive attributes at one point in time; negative attributes at another lead to inaccurate overgeneralizations	Social comparison continues although less overt	Compartmentalized attention to internalization of different standards and opinions of those in different relational contexts
Middle adolescence	Further differentiation of attributes associated with different roles and relational contexts	Initial links between single abstractions, often opposing attributes; cognitive conflict caused by seemingly contradictory characteristics; concern over which reflect one's true self	Simultaneous recognition of positive and negative attributes; instability, leading to confusion and inaccuracies	Comparisons with significant others in different relational contexts; personal fable	Awareness that the differing standards and opinions of others represent conflicting self-guides, leading to confusion over self-evaluation and vacillation with regard to behavior; imaginary audience
Late adolescence	Normalization of different role-related attributes; attributes reflecting personal beliefs, values, and moral standards; interest in future selves	Higher-order abstractions that meaningfully integrate single abstractions and resolve inconsistencies, conflict	More balanced, stable view of positive and negative attributes; greater accuracy; acceptance of limitations	Social comparison diminishes as comparisons with one's own ideals increase	Selection among alternative self-guides; construction of one's own self-standards that govern personal choices; creation of one's own ideals toward which the self aspires

velopmental changes in self-representations and self-evaluations (see Table 11.2). Second, the normative liabilities of each age period are explored. Third, the implications for pathological self-development at each age are discussed. We begin with early adolescence and a prototypical cameo.

Verbal Cameo of Normative Self-Representations and Self-Evaluations

I'm an extrovert with my friends: I'm talkative, pretty rowdy, and funny. I'm fairly good-looking, if I do say so. All in all, around people I know pretty well I'm awesome, at least I think my friends think I am. I'm usually cheerful when I'm with my friends, happy and excited to be doing things with them. I like myself a lot when I'm around my friends. With my parents, I'm more likely to be depressed. I feel sad as well as mad and also hopeless about ever pleasing them. They think I spend too much time at the mall with my friends, and that I don't do enough to help out at home. They tell me I'm lazy and not very responsible, and it's hard not to believe them. I get real sarcastic when they get on my case. It makes me dislike myself as a person. At school, I'm pretty intelligent. I know that because I'm smart when it comes to how I do in classes, I'm curious about learning new things, and I'm also creative when it comes to solving problems. My teacher says so. I get better grades than most, but I don't brag about it because that's not cool. I can be a real introvert around people I don't know well. I'm shy, uncomfortable, and nervous. Some-

times I act really dumb and say things that are just plain stupid. Then I worry about what they must think of me, probably that I'm a total dork. I just hate myself when that happens.

With regard to the content of the self-portraits of young adolescents, interpersonal attributes and social skills that influence interactions with others or one's social appeal are typically quite salient, as findings by Damon and Hart (1988) reveal. Thus, our prototypical young adolescent admits to being talkative, rowdy, funny, good-looking, and downright awesome. Presumably, these characteristics enhance one's acceptance by peers. In addition to social attributes, self-representations also focus on competencies such as one's scholastic abilities (e.g., "I'm intelligent") and affects (e.g., "I'm cheerful" and "I'm depressed").

From a developmental perspective, there is considerable evidence that during adolescence the self becomes increasingly differentiated (see Harter, 1998). There is a proliferation of selves that vary as a function of social context. These include self with father, mother, close friends, romantic partners, and peers, as well as the self in the role of student, on the job, and as an athlete (Gecas, 1972; N. Griffin, Chassin, & Young, 1981; Hart, 1988; Harter, Bresnick, Bouche, & Whitesell, 1997; Harter & Monsour, 1992; Smoller & Youniss, 1985). For example, as the cameo reveals, the adolescent may be cheerful and rowdy with friends, depressed and sarcastic with parents,

intelligent, curious, and creative as a student, and shy and uncomfortable around people he or she does not know. A critical developmental task, therefore, is the construction of multiple selves that will undoubtedly vary across different roles and relationships, as James (1892) observed over 100 years ago.

In keeping with the major themes of this chapter, both cognitive and social processes contribute to this proliferation of selves. Cognitive-developmental advances described earlier promote greater differentiation (see Fischer, 1980; Fischer & Canfield, 1986; Harter, 1990b; Harter & Monsour, 1992; Keating, 1990). Moreover, these advances conspire with socialization pressures to develop different selves in different relational contexts (see Erikson, 1968; Grotevant & Cooper, 1986; Hill & Holmbeck, 1986; Rosenberg, 1986). For example, bids for autonomy from parents make it important to define oneself differently with peers in contrast to parents (see also Steinberg & Silverberg, 1986; White, Speisman, & Costos, 1983). Rosenberg points to another component of the differentiation process in observing that as one moves through adolescence, one is more likely to be treated differently by those in different relational contexts. In studies from our own laboratory (see Harter et al., 1997; Harter & Monsour, 1992), we have found that the percentage of overlap in self-attributes generated for different social contexts ranges from 25% to 30% among seventh and eighth graders and decreases during adolescence, to a low of approximately 10% among older teenagers.

Many (although not all) of the self-descriptions to emerge in early adolescence represent abstractions about the self, based on the newfound cognitive ability to integrate trait labels into higher-order self-concepts (see Case, 1985; Fischer, 1980; Flavell, 1985; Harter, 1983; Higgins, 1991). For example, as the prototypical cameo reveals, one can construct an abstraction of the self as "intelligent" by combining such traits as smart, curious, and creative. Alternatively, one may create an abstraction that the self is a "dork" given situations where one feels dumb and "just plain stupid." Similarly, an adolescent could construct abstractions that he or she is an "extrovert" (integrating the traits of rowdy, talkative, and funny) as well as that he or she is also an "introvert" in certain situations (when one is shy, uncomfortable, and nervous). With regard to emotion concepts, one can be depressed in some contexts (combining sad, mad, and hopeless) and cheerful in others (combining happy and excited). Thus, abstractions represent more cognitively complex concepts about the self in which various trait labels can now be appropriately integrated into even higher-order generalizations.

Although the ability to construct such abstractions reflects a cognitive advance, these representations are highly compartmentalized; that is, they are quite distinct from one another (Case, 1985; Fischer, 1980; Higgins, 1991). For Fischer, these "single abstractions" are overdifferentiated, and therefore the young adolescent can think about each of them only as isolated self-attributes. According to Fischer, structures that were observed in childhood reappear at the abstract level. Thus, just as single representations were compartmentalized during early childhood, Fischer argues that when the adolescent first moves to the level of abstract thought, he or she lacks the ability to integrate the many single abstractions that are constructed to define the self in different relational contexts. As a result, adolescents will engage in all-or-none thinking at an abstract level. For Fischer, movement to a qualitatively new level of thought brings with it lack of "cognitive control"; as a result, adolescents at the level of single abstractions can think only about isolated self-attributes. Thus, contrary to earlier models of mind (Piaget, 1960), in which formal operations usher in newfound cognitive-developmental abilities that should allow one to create an integrated theory of self, fragmentation of self-representations during early adolescence is more the rule than the exception (Fischer & Ayoub, 1994; Harter & Monsour, 1992).

Another manifestation of the compartmentalization of these abstract attributes can be observed in the tendency of the young adolescent to be unconcerned about the fact that across different roles, certain postulates appear inconsistent, as the prototypical self-description implies. (In contrast, at middle adolescence, there is considerable concern.) During early adolescence, the inability to integrate seemingly contradictory characteristics of the self (intelligent versus airhead, extrovert versus introvert, depressed versus cheerful) has the psychological advantage of sparing the adolescent conflict over opposing attributes in his or her self-theory (Harter & Monsour, 1992). Moreover, as Higgins (1991) observes, the increased differentiation functions as a cognitive buffer, reducing the possibility that negative attributes in one sphere may spread or generalize to other spheres (see also Linville, 1987; Simmons & Blyth, 1987). Thus, although the construction of multiple selves sets the stage for attributes to be contradictory, most young adolescents do not identify potential contradictions or experience conflict, given the compartmentalized structure of their abstract self-representations.

Evidence for these claims comes from our own research (see Harter et al., 1997; Harter & Monsour, 1992), in which we asked adolescents at three developmental levels—early adolescence (seventh grade grade), middle

adolescence (ninth grade), and late adolescence (11th grade)—to generate self-attributes across several roles and then indicate whether any of these attributes represented opposites (e.g., cheerful versus depressed, rowdy versus calm, studious versus lazy, at ease versus self-conscious). After identifying any such opposites, they were asked whether any such pairs caused them conflict; that is, were they perceived as clashing in their personality? Across studies, the specific roles have varied. They have included self with a group of friends, with a close friend, with parents (mother versus father), in romantic relationships, in the classroom, and on the job. Across a number of converging indices (e.g., number of opposites, number of conflicts, percentage of opposites in conflict), the findings revealed that attributes identified as contradictory and experienced as conflicting were infrequent among young adolescents.

An examination of the protocols of young adolescents reveals that there are potential opposites that go undetected. Examples not identified as opposites by young adolescents (but that appeared contradictory to our research team) included being talkative as well as shy in romantic relationships, being uptight with family but carefree with friends, being both caring and insensitive with friends, being a good student as well as troublemaker in school, being self-conscious in romantic relationships but easygoing with friends, being lazy as a student but hardworking on the job. These observations bolster the interpretation, from Fischer's (1980) theory, that young adolescents do not yet have the cognitive ability to simultaneously compare these attributes to one another, and therefore they tend not to detect, or be concerned about, self-representations that are potential opposites. As one young adolescent put it, when confronted with the fact that he had indicated that he was both caring and rude, "Well, you are caring with your friends and rude to people who don't treat you nicely. There's no problem. I guess I just think about one thing about myself at a time and don't think about the other until the next day." When another young adolescent was asked why opposite attributes did not bother her, she succinctly exclaimed, "That's a stupid question. I don't fight with myself!" As will become apparent, this pattern changes dramatically during middle adolescence.

The differentiation of role-related selves beginning in early adolescence can also be observed in the tendency to report differing levels of self-esteem across relational contexts. In the prototypical description, the young adolescent reports that with friends, "I like myself a lot"; however, with parents, I "dislike myself as a person." Around "people I don't know well, I just hate myself."

In addition, although the concept of self-esteem has heretofore been reserved for perceptions of global self-esteem, we have introduced the construct of relational self-esteem (Harter, Waters, & Whitesell, 1998). Beginning in the middle school years, adolescents discriminate their level of perceived self-esteem, how much they like themselves as a person, across relational contexts. We have examined these perceptions across a number of such contexts, including self-esteem with parents, with teachers, with male classmates, and with female classmates. Factor analyses reveal clear patterns with high loadings on the designated factors (i.e., each relational context) and negligible cross-loadings. We have also examined the discrepancy between individuals' highest and lowest relational self-esteem scores. While a minority of adolescents (approximately one-fourth) were found to report little variation in self-esteem across contexts, the vast majority (the remaining three-fourths) report that their self-esteem did vary significantly as a function of the relational context. In the extreme, one female participant reported the lowest possible self-esteem score with parents and the highest possible self-esteem score with female classmates.

In addition to documenting such variability, our goal has been to identify potential causes of these individual differences. In addressing one determinant, we adopted Cooley's (1902) looking-glass self perspective, in which the opinions of significant others are incorporated into one's sense of personal worth. Building on our previous empirical efforts (see Harter, 1990b), we hypothesized that context-specific support, in the form of validation for who one is as a person, should be highly related to self-esteem in the corresponding context. The findings corroborated the more specific prediction that support within a given relationship was more highly associated with relational self-esteem in that relationship, compared to self-esteem in the other three contexts (Harter et al., 1998). Thus, the pattern of results suggests a refinement of the looking-glass self formulation, in that support in the form of validation from particular significant others will have its strongest impact on how one evaluates one's sense of worth in the context of those particular others.

These findings highlight the fact that with the proliferation of multiple selves across roles, adolescents become very sensitive to the potentially different opinions and standards of the significant others in each context. As the cameo description reveals, the adolescent reports high self-esteem around friends who think he or she is "awesome," lower self-esteem around parents who think he or she is "lazy" and "irresponsible," and the lowest level of

self-esteem around strangers, who “probably [think] that I’m a total dork.” As Rosenberg (1986) observes, adolescents demonstrate a heightened concern with the reflected appraisals of others. He notes that other people’s differing views of the self (e.g., the respect of the peer group counterposed to the critical stance of parents) will inevitably lead to variability in the self-concept across contexts.

In addition to their sensitivity to feedback from others, young adolescents continue to make use of social comparison information. However, with increasing age, children shift from more conspicuous to more subtle forms of social comparison as they become more aware of the negative social consequences of overt comparisons; for example, they may be accused of boasting about their superior performance (Pomeranz, Ruble, Frey, & Greulich, 1995). As the prototypical young adolescent describes in the cameo, “I get better grades than most, but I don’t brag about it because that’s not cool.”

Normative Liabilities for Self-Development during Early Adolescence

As with the entry into any new developmental level, there are liabilities associated with these emerging self-processes. For example, although abstractions are developmentally advanced cognitive structures, they are removed from concrete, observable behaviors and therefore are more susceptible to distortion. The adolescent’s self-concept, therefore, becomes more difficult to verify and is often less realistic. As Rosenberg (1986, p. 129) observes, when the self comes to be viewed as a collection of abstractions, uncertainties are introduced, as there are “few objective and unambiguous facts about one’s sensitivity, creativity, morality, dependability, and so on.” Moreover, the necessary skills to apply hypothetico-deductive thinking to the postulates of one’s self-system are not yet in place. Although the young adolescent may have multiple hypotheses about the self, he or she does not yet possess the ability to correctly deduce which are true, leading to distortions in self-perceptions.

The all-or-none thinking of this period, in the form of overgeneralizations that the young adolescent cannot cognitively control, also contributes to unrealistic self-representations; at one point in time, one may feel totally intelligent or awesome, whereas at another point in time, one may feel like a dork. Thus, the adolescent sense of self will vacillate, given the inability to cognitively control one’s self-representations. In describing this “barometric self” during adolescence, Rosenberg (1986) points to a different set of causes. He cites considerable literature reveal-

ing that adolescents experience an increased concern with what their peers think of them, findings that are relevant to Cooley’s (1902) looking-glass self model. This heavy dependence on the perceptions of other’s opinions tends to set the stage for volatility in one’s assessment of the self. However, there is inevitable ambiguity about others’ attitudes toward the self, as one can never have direct access to the mind of another. Thus, attributions about others’ thought processes may change from one time period to another. The second reason for fluctuating self-evaluations inheres in the fact that different significant others have different opinions of the self, depending on the situation or moment in time. Third, adolescents’ concern with what others think of them leads to efforts at impression management, provoking variations in the self across relational contexts. Finally, at times, adolescents are treated as more adult-like (e.g., on a job), whereas at other times, they are treated as more child-like (e.g., with parents at home). Thus, the self fluctuates in tandem.

Our own findings on the emergence of how self-esteem varies as a function of one’s relationships (what we have termed “relational self-esteem”) is consistent with Rosenberg’s (1986) analysis (Harter, 1999). The young adolescent is not yet troubled by what could be viewed as inconsistent self-representations because he or she cannot simultaneously evaluate them as contradictory. However, there are liabilities associated with this inability. The compartmentalization of abstractions about the self precludes the construction of an integrated portrait of self. The fact that different significant others may hold differing opinions about the self makes it difficult to develop the sense that the self is coherent. With movement into middle adolescence, abstract self-descriptors become far less isolated or compartmentalized. However, as will be demonstrated, the emerging structures that follow bring with them new liabilities.

Finally, there are domain-specific normative liabilities that are associated with educational transitions. Young adolescents all shift from an elementary school to either a middle school or a junior high school that typically draws from several elementary feeder schools. Thus, they must now move into a group of peers, many of whom they have previously not known (typically two-thirds to three-fourths of the peer group will be new). Given the young adolescent’s heightened concern with how others view the self, an important source of global self-esteem, there may be understandable shifts in global self-esteem if individuals perceive that their social acceptance is higher or lower than when they were in elementary school.

J. P. Eccles and colleagues (1989) have also pointed to different emphases within the educational system during the transition to middle school or junior high school that have implications for perceptions of one's scholastic competence. They note that there is considerably more emphasis on social comparison (public posting of grades, ability grouping; teachers, in their feedback to classes, verbally acknowledging the personal results of competitive activities). These educational practices represent a mismatch given the adolescent's needs. At a time when young adolescents are painfully self-conscious, the school system heightens the salience of social comparison in conjunction with publicizing each student's performance. In addition to the greater emphasis on social comparison, the standards for performance shift from *effort* to *ability*, according to J. P. Eccles and colleagues. They note that in elementary school, there is more emphasis on effort, that is, "Try harder and you can do better." In middle and junior high schools, however, poorer performance is attributed to lack of scholastic ability, leading the young adolescent to feel that he or she does not have the aptitude to succeed, that he or she lacks intelligence. For those not performing well, these practices can lead to declines in self-perceptions of academic ability, shifts that will be exacerbated in contexts of high public feedback and greater social comparison.

Pathological Self-Processes and Outcomes during Early Adolescence

Beginning in early adolescence, there is a heightened concern with how others view the self, a normative process that has implications for salience of those determinants of self-esteem that have been articulated in Cooley's (1902) looking-glass self formulation. If significant others provide support for who one is as a person, for those attributes that one feels truly define the self, then one will experience the self as authentic. However, the construction of a self that is too highly dependent on the internalization of the opinions of others can, under some circumstances, lead to the creation of a false self that does not mirror one's authentic experience. In our own research (Harter, 1999), we have found that it is not until early adolescence that the concept of acting as a false self becomes very salient in the consciousness of young teenagers. The detection of hypocrisy, not only in others but in oneself, emerges as a critical filter in evaluating others as well as oneself.

Our own findings (Harter, Marold, Whitesell, & Cobbs, 1996) reveal that unhealthy levels of false-self behavior are particularly likely to emerge if caregivers make their ap-

proval contingent on the young adolescent's living up to unrealistic standards of behavior based on unattainable standards dictated by parents. We have labeled this phenomenon "conditional support," although from interviews we have learned that this is a misnomer, in that adolescents do not perceive parental responses in the face of such demands as "supportive." Rather, conditionality reflects the psychological hoops through which young adolescents must jump in order to please the parents, given the parental agenda. Adolescents who experience such a conditional atmosphere are faced with the option of adopting a socially implanted self. That is, they must learn to suppress what they feel are true self-attributes in an attempt to garner the needed approval from parental caretakers. Here, the terminology purposely switches from "caregiver" to "caretaker" in a metaphorical effort to convey the fact that such socialization practices "take away" from the care of who one is as a person, from true-self development. Our findings reveal that those experiencing high levels of conditionality from parents will express hopelessness about their ability to please the parents that then translates into high levels of false-self behavior in an attempt to garner some level of needed parental support. Of particular relevance is that high levels of false-self behavior are directly related to low levels of self-esteem. As our overall model has revealed (Harter, 1999), low levels of self-esteem are highly correlated with self-reported depressive symptomatology that can, for some adolescents, lead to suicidal thoughts and actions.

Chronic and severe abuse puts one at even more extreme risk for suppressing one's true self and displaying various forms of inauthentic or false-self behavior. Such a process has its origins in childhood, in the very forms of parenting that constitute psychological abuse. As described earlier, parenting practices that lack attunement to the child's needs, fail in empathy, don't provide validation, threaten harm, coerce, and enforce compliance all cause the true self to go underground (Bleiberg, 1984; Stern, 1985; Winnicott, 1958, 1965) and lead to what Sullivan (1953) labeled "not me" experiences.

Moreover, as described in the sections on childhood, the ability to express oneself verbally allows one to falsify what is shared with others. In the maltreated child, secrecy pacts around sexually abusive interactions further provoke the child defensively to exclude such episodic memories from awareness (see also Bretherton, 1993). Thus, sexual and physical abuse cause the child to split off experiences, either consciously or unconsciously, relegating them to a private or inaccessible part of the self. The very disavowal,

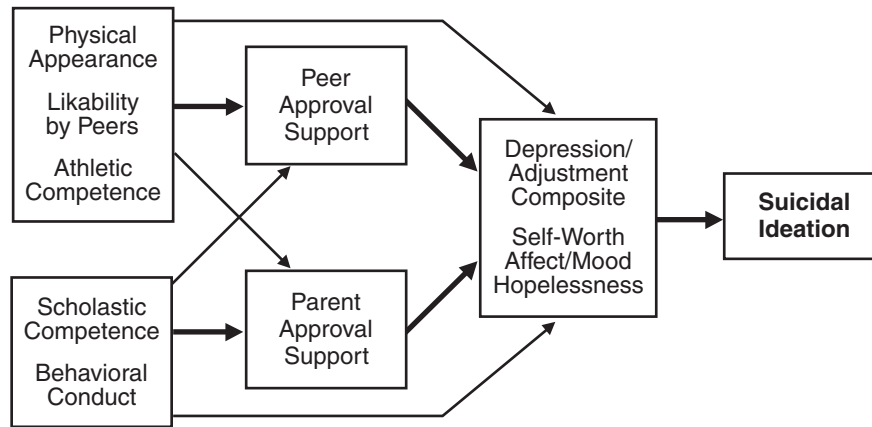

Figure 11.1 Our model of predictors and correlations of the depression/adjustment composite.

repression, or dissociation of one's experiences, coupled with psychogenic amnesia and numbing as defensive reactions to abuse, set the stage for loss of one's true self.

Herman (1992) introduces other dynamics that represent barriers to authenticity among victims of abuse. She notes that the malignant sense of inner badness is often camouflaged by the abused child's persistent attempts to be good. In adopting different roles designed to please the parent, to be the perfect child, one comes to experience one's behavior as false or inauthentic (see also A. Miller, 1990). Thus, one develops a socially acceptable false self that conforms to the demands and desires of others in an attempt to obtain their approval (see Harter et al., 1996). If one's true self, corroded with inner badness, were to be revealed, it would be met with scorn and contempt. Therefore, it must be concealed at all costs. Although these dynamics begin in childhood, during adolescence there is much more conscious awareness of these dynamics and a realization that one is being false or phony. Based on our own findings (Harter, 1999), young adolescents acknowledge that lack of parental validation and support, coupled with conditionality in which approval is contingent on meeting very high and often unrealistic standards, lead to a constellation of negative outcomes. These include high levels of false-self behavior, lack of knowledge about one's true self, depression, low self-esteem, and hopelessness. These dynamics would appear to be even more exaggerated among victims of abuse, compromising their sense of authenticity.

Our overall model of the determinants, correlates, and consequences of self-esteem (see Figure 11.1) becomes increasingly relevant at early adolescence and beyond, where there is strong empirical support across numerous studies (see review in Harter, 1999). Findings reveal that lack of both parental support and peer support can lead to patho-

logical levels of low self-worth, depressed affect, and hopelessness, which in turn may provoke suicidal ideation if not suicidal behaviors.

Our own findings (see Harter, 1999) reveal that whereas peer support increases in the predictability of global self-esteem between late childhood and early adolescence, the impact of parental support does *not* decline. Previous textbook portrayals of adolescence imply that parental influence declines as one moves into adolescence. However, nothing is further from the truth when one examines the impact of parental support, including conditionality, on self-processes, such as false-self behavior, global self-esteem, and the related correlates of depressed affect, hopelessness, and suicidal ideation.

That said, the peer culture does come to loom large in adolescence. Peer support and approval, or its absence, is a powerful predictor of what we have labeled the depression/adjustment composite that includes self-esteem, self-worth, and affect/mood along a continuum of depressed to cheerful, hopeless to hopeful, that has empirically been demonstrated to predict suicidal thinking. Lack of peer approval appears to be more directly linked to perceived inadequacies in the domains of physical appearance, likability by peers, and athletic competence.

Peer Rejection, Humiliation, and Implications for the High-Profile School Shootings. Recently, we have become more focused on the role of peer *rejection*, not merely the lack of peer approval. Our initial interest in this construct came from an analysis of the emerging profiles of the 11 high-profile cases in which White, middle-class older male children and adolescents, from small cities or suburbs, have gone on shooting sprees killing peers and, in a few cases, school officials who were random targets

rather than specifically identified individuals. In the analysis of media reports, it became evident that all of these male youth killers had a history of peer rejection and *humiliation*. As a psychologist who for many years has contributed to (and kept up with) the literature on emotional development in children and adolescents, I was astounded to learn that we have no empirical literature on humiliation. There is ample literature on shame, guilt, and embarrassment, but nothing specifically about humiliation. Yet, we can all appreciate the fact, be it from our own experience or the experience of our children, that humiliation is a daily event in most schools and in the lives of many children. Of course, for the school shooters, extreme feelings of chronic humiliation by peers due to excessive teasing, taunting, and physical insults eventually led them to psychologically “snap,” leading to random deaths and, in the case of the Columbine teens, to suicide.

An examination of the media accounts of the school shooters made it obvious that many of the determinants in our model could be found in the lives of these adolescents (see Harter, Low, & Whitesell, 2003). As a result, we examined a revised model in which we added angry aggression and violent ideation to the model. We examined this model in a normative sample of middle school students. Using path-analytic techniques, we demonstrated that the data fit the model exceedingly well. That is, the antecedents in the model, perceived inadequacies in the domains of competence and inadequacy, predicted humiliating rejection from peers and parents alike. These determinants, in turn, predicted low self-esteem, depressed affect, angry affect, and hopelessness, all of which predicted *both* suicidal ideation and violent ideation. Consistent with the clinical literature on the comorbidity of internalizing and externalizing symptoms, we found a correlation of $r = .55$ between suicidal ideation and violent ideation toward others. Thus, the determinants in our model, if negative, put adolescents at pathological risk for endangering their own, as well as others', lives.

We have also pursued more directly the emotion of humiliation and its role in contributing to violent ideation. In the Harter, Low, et al. study (2003), we wrote vignettes that simulated some of the types of humiliating events that were experienced by the school shooters. We then asked middle school students what other emotions (e.g., anger, depression) and behaviors they might experience along a continuum from do nothing to acting violently toward the perpetrators as well as toward anyone (given the randomness of the actual school shooting events). The vignettes were designed to be humiliating, and the majority of students reported that they would be humiliated. We also iden-

tified a group of violent ideators (in the minority) and compared them to those who did not report that they would think about violent revenge. We then sought to determine what distinguished the two groups, and found that those entertaining violent thoughts expressed higher levels of anger and depression. In addition, the violent ideators reported higher levels of negative determinants in the model, for example, more peer rejection, less parental support, lower self-concept scores (in terms of appearance, peer likability), lower self-worth, and greater hopelessness. Thus, certain factors in histories of violent ideators propel them to thoughts of seriously harming others as well as themselves, pathological outcomes that may require clinical interventions given that they may be putting themselves and others at serious risk.

In a subsequent study, we sought to more specifically investigate the factors that lead humiliation to result in violent ideation and suicidal ideation, given the paucity of work on the emotion of humiliation. Our findings revealed that the role of an *audience who mocks the victim* is a particularly critical determinant. Prototypical reactions include revenge, wanting to hide, and attempts to minimize the humiliation (Harter, Kiang, Whitesell, & Anderson, 2003). We are currently pursuing this prototypical approach to humiliation.

Is There a Dark Side to High Self-Esteem? Our own modeling efforts, as reported, reveal that it is *low* self-esteem that is consistently related to suicidal and violent thinking. These findings are consistent with the broader literature (see Harter, 1999) revealing that high self-esteem is a psychological commodity associated with positive adjustment and mental health outcomes. Low self-esteem, in contrast, has been viewed as a liability and has been associated with poor adjustment (e.g., depression, anxiety, conduct problems, teen pregnancy). However, currently there is controversy over whether there may also be a dark side to high self-esteem.

So what is the controversy? One group of theorists (Baumeister, Smart, & Boden, 1996) have argued that there is a subset of individuals with high but fragile self-esteem who are often aggressive in response to perceived ego threats. Baumeister et al. contend that individuals who report high self-esteem in combination with high narcissism, low empathy, and sensitivity to rejection will, in the face of threats to the ego, exhibit violent tendencies.

We (Harter & McCarley, 2004) believe that Baumeister et al.'s (1996) composite of predictors has some merit, with the exception of the role of self-esteem. Specifically, we predicted that high narcissism, low empathy, and sensitivity

to rejection coupled with *low* self-esteem (not high self-esteem) would lead young adolescents, in the face of threats to the ego, to violent ideation. To assess violent ideation, participants read humiliating scenarios that represented threats to the ego and were then asked to rate how they would typically respond in such a situation, ranging from doing nothing to seriously harming the perpetrator. Self-esteem was measured by our Global Self-Worth Scale (Harter, 1985). Narcissism, empathy, and sensitivity to rejection were assessed by adaptations of previously developed measures, all of which were found to be reliable (alphas ranging from .76 to .87). Regression analyses revealed that high narcissism and low empathy significantly predicted violent ideation. However, in contrast to Baumeister et al.'s claims, higher self-esteem was associated with lower levels of violent ideation. Further, when self-reported conduct (positive to negative) and the frequency of experiencing humiliating events were included in the model, they both explained a substantial proportion of the variance in violent ideation. In addition to regression analyses, identification of two extreme groups, those high and low on violent ideation, differed significantly with violent ideators reporting higher narcissism, lower empathy, and greater sensitivity to rejection, as Baumeister et al. would predict, but reported *lower* self-esteem that is not consistent with their formulation. In a subsequent study, we added fluctuating self-esteem, conduct, and the frequency of humiliating rejection. These increased the predictability of violence ideation, both in regression analyses and in comparisons of violent and non-violent ideators. Violent ideators reported more fluctuations in self-esteem, greater conduct problems, and a greater frequency of having established humiliating events that were ego-threatening. Thus, our understanding of the precursors of violent thoughts is enhanced given that lack of empathy and narcissism are clear predictors, although high self-esteem is not. In fact, self-esteem and narcissism correlated $-.01$, revealing that these are different constructs both conceptually, given how scales define the two constructs, and empirically. Narcissism entails a sense of entitlement, superiority, and exhibitionism, whereas high self-esteem is defined as liking and respecting who one is as a person. Clearly, there is a need to distinguish between these two concepts conceptually, methodologically, and empirically.

Finally, in this study (Harter & McCarley, 2004) we uncovered an interesting finding that is cause for concern. In the high-profile cases of the school shooters, the vast majority had not been in any major trouble with the law and had *not* come to the attention of teachers or school personnel as potential troublemakers. In fact, teachers, school officials, and students were astounded that these boys com-

mitted such violent acts. Debriefing efforts of the surviving students and families at Columbine, conducted by University of Denver clinicians and some in private practice, revealed that students and their families were realistically fearful that they would not be able to detect who, in the future, might commit such acts because there were few warning signs that the shooters were capable of such behavior. These concerns are real, given findings from Harter and McCarley (2004). In this study, we asked teachers to rate student conduct (getting in trouble, potential for violent thinking). Among the subgroup of violent ideators who had rated their own conduct as quite negative, teachers misrated one-third of the group, giving them very positive scores on conduct. This is concerning with regard to the difficulty in assessing certain students as being at risk. Although such violent ideators may not be at risk for violent *action* (given the low percentage of such acts in most schools), violent ideation represents a different kind of pathological risk factor to the extent that it interferes with attention to and concentration on scholastic endeavors, with socially appropriate behaviors that would promote positive peer interactions and so on. The very presence of this subgroup of violent ideators suggests that they represent a type of student with intrapsychic dynamics that are different from those students with histories of conduct problems, delinquency, and acting-out patterns, all of whom readily come to the attention of teachers, school officials, and students. Those not showing these patterns are of concern in terms of their identification. One of our goals is to devise a short form of our instruments that will allow schools to identify those who may have escaped the attention of school personnel but are nevertheless at pathological risk. Many of these processes begin in early adolescence (and even late childhood) but continue into middle and later adolescence, as the range of ages of the actual school shooters reveals, continuing the presence of risk factors.

Pathological Eating-Disordered Behavior. Our model identifies one self-concept domain that robustly affects global self-esteem across ages and cultures, namely, perceived physical appearance or attractiveness. In reviewing the inextricable link between perceived appearance and self-esteem, between the outer self and the inner self (see Harter, 1999), it became very apparent that this link is profoundly impacted by cultural standards of appearance for each gender. That cultures tout physical attractiveness as the measure of one's worth as a person has been amply demonstrated in contemporary society, as well as historically (Hatfield & Sprecher, 1986). The empirical findings

(reviewed in Harter, 1999) reveal that correlations range from the 40s to the 80s. Moreover, investigators have revealed that these relationships are not merely statistical but are very much embedded in the consciousness of individuals who are aware of this link. In our own work (Kiang & Harter, 2004), we have found strong support for a model in which awareness of current cultural values (e.g., being attractive will lead to higher self-esteem, meeting standards of appearance will make people more popular, people who are overweight are discriminated against) are highly endorsed. However, there is variability in these scores. Such awareness predicts perceptions of one's own appearance, which in turn predicts level of self-esteem and eating-disordered perceptions and behaviors. Specifically, those endorsing these cultural values or links report more negative views of their appearance, lower self-esteem, more psychological correlates of eating disorders, and more eating-disordered behaviors.

This particular study was conducted with college students. However, the seeds of such a model are sown in early adolescence (if not earlier) as teenagers of both genders are well aware of the prevailing norms for desirable appearance. For adult females in the 2000s, one must be tall, very thin, weigh very little (around 110 to 115), have ample breasts, and, of course, have a pretty face and hair, an unattainable combination for more than 90% of the female population. (Recent statistics from a September, 2004 National Public Radio [NPR] report indicated that the average American woman is 5'4" and weighs 140.) Standards have been exceedingly punishing for females for decades. What is new within the past 2 decades is the fact that the bar has been raised for males in our society. No longer is appeal to be judged by status, wealth, position, and power but by physical standards of attractiveness as well. Muscular build (strong abs and biceps), good physique, and attractive hair (on head as well as face) have all come to define the new ideals for men (see Harter, 1999).

These standards are not lost on our young adolescents. In fact, children succumb to the same discouragement as adults about not being able to emulate the models, singers, and movie stars in the limelight. The importance of meeting these standards becomes particularly salient during early adolescence, as teenagers face inevitable pubertal changes that signal their impending adulthood. Thus, they look to the adult standards as the physical markers for what defines attractiveness, appeal, and social acceptability, all of which determine one's self-esteem.

The genetic throw of the dice leads some young adolescent males and females to fare better than others in the appearance wars. For example, early-maturing girls are at a

distinct disadvantage given the current emphasis on thinness and height because on average they are heavier and shorter compared to later-maturing girls. The pattern is just the opposite for adolescent males; earlier-maturing males tend to be taller and more muscular, which gives them a physical edge. Thus, beginning in earnest during early adolescent, evaluations of one's appearance take on critical implications for one's global self-esteem. Those not meeting the gold standard are at serious risk for pathological forms of depression and possibly suicide as well as eating disorders that can be life-threatening. Although this preoccupation initially becomes quite salient in early adolescence, it continues throughout the life span.

Middle Adolescence

Unlike more classic treatments of development in which adolescence is treated as one stage, more recent theory and empirical research (see Harter, 1999) reveals that with regard to self-processes there are three definable substages during the teenage years. The period of middle adolescence is markedly different, in terms of representations of the self, from the preceding stage of early adolescence as well as the stage that follows in late adolescence and early adulthood. It is a fascinating stage in that while there are cognitive advances, these also represent psychological minefields. The normative features of self-development necessarily overlaps with a discussion of the liabilities at this age level. However, these are contrasted to more pathological processes that may emerge in middle adolescence.

Verbal Cameo of Normative Self-Representations and Self-Evaluations

What am I like as a person? You're probably not going to understand. I'm complicated! With my really close friends, I am very tolerant. I mean, I'm understanding and caring. With a group of friends, I'm rowdier. I'm also usually friendly and cheerful, but I can get pretty obnoxious and intolerant if I don't like how they're acting. I'd like to be friendly and tolerant all of the time, that's the kind of person I want to be, and I'm disappointed in myself when I'm not. At school, I'm serious, even studious every now and then, but on the other hand, I'm a goof-off too, because if you're too studious, you won't be popular. So I go back and forth, which means I don't do all that well in terms of my grades. But that causes problems at home, where I'm pretty anxious when I'm around my parents. They expect me to get all As, and get pretty annoyed with me when report cards come out. I care what they think about me, and so then I get down on myself, but it's not fair! I mean, I worry about how I probably should get better grades, but I'd be mortified in the eyes of my friends if I did too well.

So, I'm usually pretty stressed-out at home, and can even get very sarcastic, especially when my parents get on my case. But I really don't understand how I can switch so fast from being cheerful with my friends, then coming home and feeling anxious, and then getting frustrated and sarcastic with my parents. Which one is the real me? I have the same question when I'm around boys. Sometimes, I feel phony. Say I think some guy might be interested in asking me out. I try to act different, like Britney Spears, I'll be a real extrovert, fun-loving and even flirtatious, and think I am really good-looking. It's important to be good-looking like the models and movie stars. That's what makes you popular. I know in my heart of hearts that I can never look like her, so why do I even try? It makes me hate myself and feel depressed. Plus, when I try to look and act like her, then everybody, I mean *everybody* else is looking at me like they think I am totally weird! They don't act like they think I'm attractive, so I end up thinking I look terrible. I just hate myself when that happens! Because it gets worse! Then I get self-conscious and embarrassed and become radically introverted, and I don't know who I really am! Am I just acting like an extrovert, am I just trying to impress them, when really I'm an introvert? But I don't really care what they think, anyway. I mean, I don't want to care, that is. I just want to know what my close friends think. I can be my true self with my close friends. I can't be my real self with my parents. They don't understand me. What do they know about what it's like to be a teenager? They treat me like I'm still a kid. At least at school, people treat you more like you're an adult. That gets confusing, though. I mean, which am I? When you're 15, are you still a kid or an adult? I have a part-time job and the people there treat me like an adult. I want them to approve of me, so I'm very responsible at work, which makes me feel good about myself there. But then I go out with my friends and I get pretty crazy and irresponsible. So, which am I, responsible or irresponsible? How can the same person be both? If my parents knew how immature I act sometimes, they would ground me forever, particularly my father. I'm real distant with him. I'm pretty close to my mother, though. But it's hard being distant with one parent and close to the other, especially if we are all together, like talking at dinner. Even though I am close to my mother, I'm still pretty secretive about some things, particularly the things about myself that confuse me. So I think a lot about who is the real me, and sometimes I try to figure it out when I write in my diary, but I can't resolve it. There are days when I wish I could just become immune to myself!

Self-descriptions are likely to increase in length during this period, as adolescents become increasingly introspective as well as morbidly preoccupied with what others think of them (Broughton, 1978; Elkind, 1967; Erikson, 1959, 1968; Harter, 1990a; Lapsley & Rice, 1988; Rosenberg, 1979). The unreflective self-acceptance of earlier

periods of development vanishes, and, as Rosenberg observes, what were formerly unquestioned self-truths now become problematic self-hypotheses. The tortuous search for the self involves a concern with what or who I am (Broughton, 1978), a task made more difficult given the multiple Me's that crowd the self-landscape. There is typically a further proliferation of selves as adolescents come to make finer differentiations; in the cameo, the adolescent describes a self with really close friends (e.g., tolerant) versus with a group of friends (e.g., intolerant) and a self with mother (e.g., close) versus father (e.g., distant). The acquisition of new roles, for example, self at a job, may also require the construction of new context-specific attributes (e.g., responsible).

Moreover, additional cognitive I-self processes emerge that give the self-portrait a very new look (Case, 1985; Fischer, 1980). Whereas, in the previous stage, single abstractions were isolated from one another, during middle adolescence one acquires the ability to make comparisons between single abstractions, that is, between attributes within the same role-related self or across role-related selves. Fischer labels these new structures "abstract mappings"; the adolescent can now "map" constructs about the self onto one another, directly comparing them. Mappings thus force the individual to compare and contrast different attributes. It should be noted that abstract mappings have features in common with the "representational" mappings of childhood, in that the cognitive links that are initially forged often take the form of opposites. During adolescence, these opposites can take the form of seemingly contradictory abstractions about the self (e.g., tolerant versus intolerant, extrovert versus introvert, responsible versus irresponsible, good-looking versus unattractive, as in the cameo).

However, the abstract mapping structure has limitations as a means of relating two concepts to one another, in that the individual cannot yet truly integrate such self-representations in a manner that would resolve apparent contradictions. Therefore, at the level of abstract mappings, the awareness of these opposites causes considerable intrapsychic conflict, confusion, and distress (Fischer et al., 1984; Harter & Monsour, 1992; Higgins, 1991) given the inability to coordinate these seemingly contradictory self-attributes. For example, our prototypical adolescent agonizes over whether she is an extrovert or an introvert ("Am I just acting like an extrovert, am I just trying to impress them, when really I'm an introvert?"; "So which am I, responsible or irresponsible? How can the same person be both?"). Such cognitive-developmental limitations contribute to the emer-

gence of what James (1892) identified as the “conflict of the different Me’s.”

In addition to such confusion, these seeming contradictions lead to very unstable self-representations, which is also cause for concern (e.g., “I don’t really understand how I can switch so fast from being cheerful with my friends, then coming home and feeling anxious, and then getting frustrated and sarcastic with my parents. Which one is the real me?”). The creation of multiple selves, coupled with the emerging ability to detect potential contradictions between self-attributes displayed in different roles, naturally ushers in concern over which attributes define the true self. However, from a normative perspective, the adolescent at this level is not equipped with the cognitive skills to solve fully the dilemma (e.g., “So I think a lot about who is the real me, and sometimes try to figure it out when I write in my diary, but I can’t resolve it”).

As introduced in the section on early adolescence, our own research has been directed toward an examination of the extent to which adolescents at three developmental levels both identify opposing self-attributes and report that they are experienced as conflictual (Harter et al., 1997; Harter & Monsour, 1992). Across several studies, we have determined that young adolescents infrequently detect opposites within their self-portrait. However, it was predicted, according to the analysis presented earlier, that there would be a dramatic rise in the detection of opposing self-attributes as well as an acknowledgment that such apparent contradictions lead to conflict within the self-system. Our most recent procedure for examining these issues is illustrated in the protocol presented in Figure 11.2. Adolescents are first asked to generate six attributes for each role, writing them on the lines associated with each interpersonal context. These contexts have varied from study to study; however, in the sample protocol, we asked them to generate attributes for six roles: self with mother, with father, with a romantic interest, with their best friend, with a group of friends, and in their role as student in the classroom. As in our original procedure (Harter & Monsour, 1992), respondents were then asked to identify any pairs of attributes they perceived to reflect opposites, by connecting them with lines. Next, they indicated whether any of these opposites were experienced as clashing or in conflict with each other, by putting arrowheads on the lines connecting those pairs of opposites.

Across three different studies (see Harter et al., 1997), we have found that the number of opposing self-attribute pairs, as well as the number of opposites in conflict, increases between early and middle adolescence. This pattern of findings supports the hypothesis that the abstract

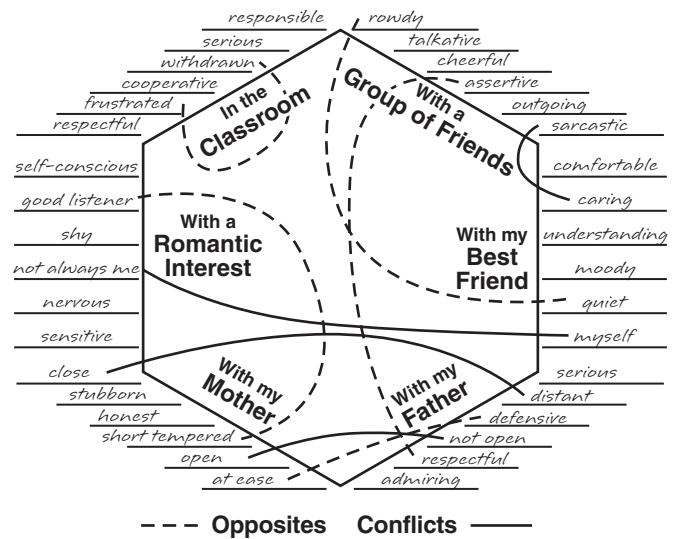

Figure 11.2 Prototypical self-portrait of a 15-year-old girl.

mapping structures that emerge in middle adolescence allow one to detect, but not to meaningfully integrate, these apparent contradictions. Thus, they lead to the phenomenological experience of intrapsychic conflict. We have asked teenagers to verbally elaborate on the opposites and conflicts that they reported on our task. As one 14-year-old put it, “I really think I am a happy person and I want to be that way with everyone, not just my friends; but I get depressed with my family, and it really bugs me because that’s not what I want to be like.” Another 15-year-old, in describing a conflict between self-attributes within the realm of romantic relationships, exclaimed, “I hate the fact that I get so nervous! I wish I wasn’t so inhibited. The real me is talkative. I just want to be natural, but I can’t.” Another 15-year-old girl explained, “I really think of myself as friendly and open to people, but the way the other girls act, they force me to become an introvert, even though I know I’m not.” In exasperation, one ninth grader observed of the self-portrait she had constructed, “It’s not right, it should all fit together into one piece!” These comments suggest that at this age level, there is a need for coherence; there is a desire to bring self-attributes into harmony with one another. Yet, in midadolescence, the cognitive abilities to create such a self-portrait are not yet in place.

An examination of the protocol in Figure 11.2 illustrates the fact that adolescents can identify two types of opposing attributes, those occurring within a given role (e.g., frustrated and withdrawn in the classroom) and those occurring across relational contexts (e.g., close with mother but distant with father; rowdy with a group of friends but quiet

with one's best friend). We became curious about whether there were more opposing attributes and associated conflict within particular roles (e.g., rowdy versus withdrawn with friends). Among those social psychologists who have focused on the adult self, it has been argued that consistency within a particular relationship is critical; therefore, perceived violations of this consistency ethic, where one displays opposing attributes within a role, should be particularly discomforting to the individual (Gergen, 1968; Vallacher, 1980). According to these theorists, the adoption of different behaviors in different roles should be less problematic or conflictual for adults, because they represent appropriate adaptation to different relational contexts rather than inconsistency.

From a developmental perspective, we did not expect these processes to be in place during adolescence. Adolescents are actively concerned with creating, defining, and differentiating role-related selves, and thus there is relatively little overlap in the self-attributes associated with different roles. Moreover, opposing attributes across relational contexts become more marked or salient in midadolescence, when teenagers develop the cognitive ability to detect seeming contradictions. The very salience of these opposites leads to a greater focus on contradictions across roles rather than within roles. Perceived conflict caused by opposing attributes should also be greater across roles, particularly with the onset of midadolescence, when teenagers can begin to compare characteristics across such roles but cannot integrate these salient and seemingly contradictory self-attributes. As can be seen in Figure 11.3, the number

Figure 11.3 Gender differences in the number of opposing attributes identified across roles.

of opposites identified at midadolescence and beyond is far greater for attributes identified across roles than within each role, confirming our expectation. The pattern was obtained for opposites in conflict.

Figure 11.3 also reveals that for across-role opposites, at every age level, females detect more contradictory attributes than do males. These findings replicate two other studies in which similar gender differences were obtained (see Harter et al., 1997). Moreover, in one study in which we asked subjects to indicate how upset they were over conflicting attributes, the pattern revealed that females become more upset over conflicting attributes across early, middle, and late adolescence, whereas males become less upset. Elsewhere, we have offered a general interpretation of this pattern, drawing on those frameworks that emphasize the greater importance of relationships for females than males (Chodorow, 1989; Eichenbaum & Orbach, 1993; Gilligan, 1982; Jordan, 1991; J. B. Miller, 1986; Rubin, 1985). These theorists posit that the socialization of girls involves far more embeddedness within the family, as well as more concern with connectedness to others. Boys, in contrast, forge a path of independence and autonomy in which the logic of moral and social decisions takes precedence over affective responses to significant others.

In extrapolating from these observations, we have suggested that in an effort to maintain the multiple relationships that girls are developing during adolescence, and to create harmony among these necessarily differentiated roles, opposing attributes within the self become particularly salient as well as problematic. Boys, in contrast, can move more facily among their different roles and multiple selves to the extent that such roles are logically viewed as more independent of one another. However, these general observations require further refinement, including an empirical examination of precisely which facets of the relational worlds of adolescent females and males are specifically relevant to gender differences in opposing attributes displayed across different contexts.

Closer examination of the gender effects reveals that it is a subset of female adolescents who report more opposites and greater conflict compared to males. We have determined that adolescent females who endorse a feminine gender orientation (eschewing masculine traits) may be particularly vulnerable to the experience of opposing attributes and associated conflict. Feminine adolescent females, compared to females who endorse an androgynous orientation, report more conflict, particularly in roles that involve teachers, classmates, and male friends (in contrast to roles involving parents and female friends). Several hy-

potheses would be worth pursuing in this regard. Is it that feminine girls report more contradictions in those public contexts where they feel they may be acting inappropriately by violating feminine stereotypes of behavior? Given that femininity as assessed by sex-role inventories is largely defined by caring, sensitivity, and attentiveness to the needs and feelings of others, might female adolescents who adopt this orientation be more preoccupied with relationships, making opposing attributes and accompanying conflict more salient? Moreover, might it be more important for feminine girls to be consistent across relationships, a stance that may be difficult to sustain to the extent that significant others in different roles are encouraging or reinforcing different characteristics? These are all new directions in which attention to gender issues should proceed.

The challenges posed by the need to create different selves are also exacerbated for ethnic minority youth in this country, who must bridge "multiple worlds," as Cooper and her colleagues point out (Cooper, Jackson, Azmitia, Lopez, & Dunbar, 1995). Minority youth must move between multiple contexts, some of which may be with members of their own ethnic group, including family and friends, and some of which may be populated by the majority culture, including teachers, classmates, and other peers who may not share the values of their family of origin. Rather than assume that all ethnic minority youth will react similarly to the need to cope with such multiple worlds, these investigators have highlighted several different patterns of adjustment. Some youth are able to move facily across the borders of their multiple worlds, in large part because the values of the family, teachers, and peers are relatively similar. Others, for whom there is less congruence in values across contexts, adopt a bicultural stance, adapting to the world of family as well as to that of the larger community. Others find the transition across these psychological borders more difficult, and some find it totally unmanageable. Particularly interesting is the role that certain parents play in helping adolescents navigate these transitions, leading to more successful adaptations for some than others.

As observed earlier, adolescents during this period become extremely preoccupied with the opinions and expectations of significant others in different roles. As our prototypical respondent indicates, "I care what my parents think about me"; "I want to know what my close friends think"; "I don't care what [everybody else] thinks. I mean, I don't want to care, that is"; "I want [adults at work] to approve of me"; that is, adolescents gaze intently into the social mirror for information about what standards and

attributes to internalize. However, as the number of roles proliferate, leading to messages from different significant others that are potentially contradictory, adolescents may become confused or distressed about just which characteristics to adopt. We see this in the cameo self-description with regard to scholastic performance, in that the adolescent feels she "should get better grades" to please her parents but confesses that "I'd be mortified in the eyes of my friends if I did too well." As Higgins (1991) observes, in their attempt to incorporate the standards and opinions of others, adolescents at this level develop conflicting "self-guides" across different relational contexts as they attempt to meet the incompatible expectations of parents and peers. He reports evidence indicating that such discrepancies have been found to produce confusion, uncertainty, and indecision with regard to self-evaluation and self-regulation, consistent with our own findings. Moreover, as Rosenberg (1986) notes, the serious efforts at perspective taking that emerge at this stage make one aware that no human being can have direct access to another's mind, leading to inevitable ambiguity about others' attitudes toward oneself, producing yet another source of doubt and confusion.

The potential for displaying differing levels of self-esteem across relational contexts is also exacerbated during this period, to the extent that significant others are providing different levels of validation for who one is as a person (see also Rosenberg, 1986). For example, the cameo self-description reveals that the adolescent gets down on herself for not getting the grades her parents expect. She hates herself when she feels peers think she is weird, but she feels good about herself on the job, where supervisors give her more positive feedback. Our own evidence has revealed that not only does self-esteem become differentiated by context beginning in early adolescence, but it becomes further differentiated in middle to late adolescence. For example, individuals come to develop different levels of self-esteem with their mother and their father (Harter, 1999), levels that in turn are directly related to their perceptions of approval from each parent.

Normative Liabilities during Middle Adolescence

Midadolescence brings with it a preoccupation with what significant others think of the self, a task that is made more challenging given the proliferation of roles that demand the creation of multiple selves. The addition of new role-related selves can be observed in the fact that adolescents make finer discriminations, for example, self with a close friend versus self with a group of friends, and self with mother versus self with father. Moreover, there is relatively little

overlap in the personal attributes that define the self in each role. The proliferation of multiple selves ushers in the potential for such attributes to be viewed as contradictory. Moreover, the emergence of new cognitive processes such as abstract mappings forces the adolescent to compare and contrast different attributes, exacerbating the likelihood that contradictions will be detected. Mapping, in the form of identification of opposites, is problematic, as the individual cannot yet truly integrate such self-representations in a manner that would resolve the contradictions. Thus, the adolescent is likely to experience conflict, confusion, and distress. Opposites and associated conflict are particularly likely to occur for attributes in different roles, rather than in the same role. Females are particularly likely to display these negative outcomes. Opposing self-attributes also lead to unstable self-representations, in addition to concern over which characteristics represent one's true self.

With regard to the impact of the socializing environment, adolescents gaze intently into the social mirror for information about what standards and attributes to internalize. However, contradictory messages from different significant others can lead to confusion about just what characteristics to adopt. Differential support, in the form of approval or validation, will also lead to differing levels of self-worth across relational contexts. The contradictory feedback that adolescents may receive from different sources will, therefore, lead to volatility in self-esteem across interpersonal contexts.

Contradictory standards and feedback can also contribute to a lowering of global self-esteem between early and midadolescence (see findings reviewed by Harter, 1990a), to the extent that one cannot meet the expectations of everyone in each relational context. Given that the adolescent does not meet the standards of others, he or she is likely to experience less approval, which in turn will lead to lower global self-esteem. Moreover, the abstract mapping structure, coupled with the penchant for introspection, may also contribute to lowered self-esteem because it facilitates the comparison of one's ideal and real self-concepts. Such a focus can lead to a heightened awareness of the discrepancy between how one perceives the self to be in reality (e.g., "I can get pretty obnoxious and intolerant") and how one would ideally like to be (e.g., "I'd like to be friendly and tolerant all of the time. That's the kind of person I want to be, and I'm disappointed in myself when I'm not"). The realm of physical appearance is particularly critical. This adolescent wants to look like Britney Spears and knows she doesn't, and this sets up another painful discrepancy between how she would like to look and how she

actually does. In reality, she does not value her appearance, falling far short of the cultural standards for beauty.

Cognitive-developmental advances during midadolescence also represent limitations that can lead to distortions in the interpretation of the opinions of significant others. As observed earlier, with new cognitive capacities comes difficulty in controlling and applying them effectively. For example, teenagers have difficulty differentiating their own mental preoccupations from what others are thinking, leading to a form of adolescent egocentrism that Elkind (1967) has labeled the "imaginary audience." Adolescents falsely assume that others are as preoccupied with their behavior and appearance as they themselves are. As our prototypical respondent exclaims, "Everybody, I mean everybody else is looking at me like they think I am totally weird!" With regard to lack of cognitive control, this phenomenon represents overgeneralization (or failure to differentiate) as adolescents project their own concerns onto others.

Interestingly, the inability to control and to effectively apply new cognitive structures can result not only in a lack of differentiation between self and other, as in the imaginary audience phenomenon, but also in excessive or unrealistic differentiation. The latter penchant can be observed in another form of adolescent egocentrism that Elkind (1967) has identified as the "personal fable." In creating narratives that come to define the self, the adolescent asserts that his or her thoughts and feelings are uniquely experienced. No one else can possibly understand or experience the ecstasy of his or her rapture or the intensity of his or her despair. Adults, particularly parents, are likely to be singled out in this regard. As the prototypical adolescent exclaims, "My parents don't understand me. What do they know about what it's like to be a teenager?" Her initial comment to the interviewer when asked to describe what she was like ("You're probably not going to understand") also reflects this type of overdifferentiation between self and other.

The liabilities of this period, therefore, are legion with regard to potential conflict and confusion over contradictory attributes and messages, concern over which characteristics define the true self, distortions in the perception of self versus others, and a preoccupation with discrepancies between the real and ideal self-concepts that can lead to lowered self-esteem. Some of these processes would appear to be problematic for particular subgroups of adolescents, for example, females who adopt a feminine gender orientation and ethnic minority youth who are challenged by the need to create selves that bridge "multiple worlds," for example, with one's own ethnic group and groups within the mainstream majority culture.

An appreciation for the ramifications of these normative processes is critical in interpreting the unpredictable behaviors, shifting self-evaluations, and mood swings that are observed in many adolescents during this age period. Such displays are less likely to be viewed as intentional or pathological and more likely to meet with empathy and understanding to the extent that normative cognitive-developmental changes can be invoked as in part responsible. For many parents, as well as other adults working closely with teenagers, these seemingly inexplicable reactions often lead to perplexity, exasperation, and anger, provoking power struggles and altercations that strain the adolescent-adult relationship. The realization that this is a normative part of development that should not persist forever may provide temporary comfort to adults who feel beleaguered and ineffectual in dealing with adolescents of this age. Indeed, it gives a more charitable rendering to this period of development.

Much of the preceding discussion has focused on normative liabilities based on the *cognitive-developmental* changes in the *structure* of adolescent thought at this period. However, there are also normative liabilities that can stem from the *content* of the adolescent self-portrait. Our prototypical female adolescent aspires to look like Britney Spears, given the importance of physical appearance that increases during adolescence. However, like the majority of adolescents, she cannot meet the punishing standards put forth by the media that define today's ideals for beauty (Harter, 1999). The demand that one be excessively thin, tall, and long-legged, with ample breasts and a pretty face is an ideal that the vast majority of females in this culture cannot attain (Kilbourne, 1994). Applying a Jamesian (James, 1892) perspective, the discrepancy between the extreme importance attached to appearance and perceptions of inadequacy in one's appearance can set the stage for lowered self-esteem for females. The problem is exacerbated for females whose pubertal development does not favor the cultural ideal of beauty (Harter, 1999). With the onset of puberty, girls put on body fat and hips become wider, each of which violates the norms of thinness, one criterion for physical attractiveness. Males are more favored because puberty brings about physical changes more in keeping with the contemporary norms of male attractiveness. Males become taller and more muscular, attributes that are valued by society. Many of these normative liabilities interact, in that there can be conflict and confusion over one's self-attributes, for example, vacillations in whether one feels attractive or unattractive. However, as we shall see in the next section, taken to the extreme, in

some individuals these can lead to more pathological processes and outcomes.

Pathological Self-Processes and Outcomes in Middle Adolescence

With regard to a focus on meeting cultural standards of appearance, females are much more likely to suffer from processes that move into the realm of pathology. From the perspective of our own model of the causes and correlates of self-esteem, an intense preoccupation with attempts to meet the impossible standards of beauty, coupled with very negative perceptions of one's body image, can lead to extremely low self-esteem, depression, and, in the extreme, eating-disordered behaviors. We have documented the links between the high importance attached to physical appearance and negative perceptions of one's body image, leading to extremely negative reports of self-esteem and depression, among those in midadolescence. In the subsequent section on later adolescence and emerging adulthood, we provide further documentation about how these processes can lead to pathological eating-disordered behaviors.

Numerous findings (reviewed in Harter, 1999; see also Nolen-Hoeksema & Girgus, 1994) reveal that dramatic gender differences in depression emerge in middle adolescence. The discrepancy between impossible ideals of appearance and one's perception of one's own body image contributes to very low self-esteem for some, particularly those who are overweight, that in turn leads to profound depression that can require clinical intervention.

The potential for such internalizing symptoms looms large for girls during middle adolescence. The potential for the escalation of violence, as in the case of the high-profile cases of school shootings by White, middle-class adolescents, is also apparent. Intense rejection by peers, at a time when self-consciousness and the need for approval are so salient, sets the stage for violent ideation that can turn to action. The fragile and vacillating self-structures of this particular period can, in the face of such humiliation, lead to lack of control, both over cognitions about the self (Harter, 1999) and behaviors that these cognitions may drive. Given the lack of cognitive control (Fischer, 1980), the adolescent during this period may act more impulsively on his or her thoughts. Recent work on the adolescent brain supports the view that the frontal cortex is not yet completely developed, leading to gaps in executive functions that could serve to curb such impulsive, violent intentions and behaviors.

While the fragmented self is a normative liability of this period of middle adolescence, a history of severe and

chronic physical and sexual abuse may lead to pathological outcomes. The effects of abuse on the self-system are legion (see review in Harter, 1999). From a developmental perspective, a history of abuse can lead to dissociative symptoms that serve to further fragment the fragile multiple selves in the process of psychological construction (see also Putnum, 1993; Westen, 1993). As a result, there is no core self at the helm, and there is little communication between multiple selves that become “alters,” compromising the ability to develop an integrated self. As a result, there is the risk for dissociative identity disorders that represent severe pathological conditions that may require years of treatment.

Late Adolescence

Our final period, late adolescence that may extend into early adulthood, is critical to characterize because many of the conflicts and confusions of the preceding period of middle adolescence decline, normatively. The verbal cameo and subsequent analysis illustrate these changes. There are fewer liabilities with the ensuing developmental advances. However, the shift to higher levels of abstraction bring new challenges in terms of self-definition. These are described, as well as pathological implications for teenagers emerging into young adulthood.

Verbal Cameo of Normative Self-Representations and Self-Evaluations

I'm a pretty conscientious person, particularly when it comes to things like doing my homework. It's important to me because I plan to go to college next year. Eventually I want to go to law school, so developing good study habits and getting top grades are both essential. (My parents don't want me to become a lawyer; they'd rather I go into teaching, but law is what I want to pursue.) Every now and then I get a little lackadaisical and don't complete an assignment as thoroughly or thoughtfully as I could, particularly if our high school has a big football or basketball game that I want to go to with my friends. But that's normal, I mean, you can't just be a total grind. You'd be pretty boring if you were. You have to be flexible. I've also become more religious as I have gotten older, not that I am a saint or anything. Religion gives me a sense of purpose, in the larger scheme of things, and it provides me with personal guidelines for the kind of adult I'd like to be. For example, I'd like to be an ethical person who treats other people fairly. That's the kind of lawyer I'd like to be, too. I don't always live up to that standard; that is, sometimes I do something that doesn't feel that ethical. When that

happens, I get a little depressed because I don't like myself as a person. But I tell myself that it's natural to make mistakes, so I don't really question the fact that deep down inside, the real me is a moral person. Basically, I like who I am, so I don't stay depressed for long. Usually, I am pretty upbeat and optimistic. I guess you could say that I'm a moody person. I'm not as popular as a lot of other kids. You have to look a certain way, have the right body image, wear the right clothes, to be accepted. At our school, it's the jocks who are looked up to. I've never been very athletic, but you can't be good at everything, let's face it. Being athletic isn't that high on my own list of what is important, even though it is for a lot of kids in our school. I try to think that, anyway. But I don't really care what they think anymore, at least I try to convince myself that I don't. I try to believe that what I think is what counts. After all, I have to live with myself as a person and to respect that person, which I do now, more than a few years ago. I'm pretty much being the kind of person I want to be. I'm doing well at things that are important to me, like getting good grades. That's what is probably most important to me right now. Having a lot of friends isn't that important to me. I wouldn't say I was unpopular, though. While I am basically an introvert, especially on a date when I get pretty self-conscious, in the right social situation, like watching a ball game with my friends, I can be pretty extroverted. You have to be adaptive around other people. It would be weird to be the same kind of person on a date and with my friends at a football game! For example, when our team has a winning season and goes to the playoffs, everyone in the whole school is proud; what the team does reflects on all of us. On a date, the feelings are much more intimate, just between you and the other person. As much as I enjoy my high school friends and activities, I'm looking forward to leaving home and going to college, where I can be more independent, although I'm a little ambivalent. I love my parents, and really want to stay connected to them, plus, what they think about me is still important to how I feel about myself as a person. So leaving home will be bittersweet. But sometimes it's hard to be mature around them, particularly around my mom. I feel a lot more grown-up around my dad; he treats me more like an adult. I like that part of me because it feels more like my true self. My mom wants me to grow up, but another part of her wants me to remain “her little baby.” I'll probably always be somewhat dependent on my parents. How can you escape it? But I'm also looking forward to being on my own.

With regard to the content of the self-representations that begin to emerge in late adolescence and early adulthood, typically, many of the attributes reflect personal beliefs, values, and moral standards that have become internalized or, alternatively, constructed from one's own experiences (see findings by Damon & Hart, 1988). These characteristics are exemplified in the prototypical cameo, as the ado-

lescent expresses the personal desire to go to college, which requires good grades and discipline in the form of study habits. Although classmates tout athletics as the route to popularity, there is less concern at this age with what others think (“I don’t really care what they think anymore, at least I try to convince myself that I don’t”). In addition, there is a focus on one’s future selves, for example, not only becoming a lawyer, but also an ethical lawyer, as a personal goal. Noteworthy in this narrative is the absence of an explicit reference to the potential origins of these goals, for example, parental encouragement or expectations that one pursue such a career. Moreover, this adolescent’s career choice does not conform to the parents’ occupational goals for their child.

The failure to acknowledge the socialization influences that might have led to these choices does not necessarily indicate that significant others such as peers and parents had no impact. In fact, findings (see Steinberg, 1990) reveal that the attitudes of adolescents and their parents are quite congruent when it comes to occupational, political, and religious decisions and convictions. Rather, the fact that the impact of significant others is not acknowledged suggests that older adolescents and young adults have come to “own” various values as personal choices rather than attribute them to the sources from which they may have been derived (Damon & Hart, 1988). In Higgins’s (1991) terminology, older adolescents have gone through a process in which they have actively selected among alternative self-guides and are no longer merely buffeted about by the expectations of significant others; that is, self-guides become increasingly internalized and less tied to their social origins. Moreover, there is a greater sense of direction as the older adolescent comes to envisage future or “possible” selves (Markus & Nurius, 1996) that function as ideals toward which one aspires.

Another feature of the self-portrait of the older adolescent can be contrasted with the period before; now, many potentially contradictory attributes are no longer described as characteristics in opposition to one another. Thus, being conscientious as a student does not appear to conflict with one’s lackadaisical attitude toward schoolwork: “That’s normal, I mean, you can’t just be a total grind. You’d be pretty boring if you were. You have to be flexible.” Similarly, one’s perception of the self as ethical does not conflict with the acknowledgment that one also has engaged in some unethical behaviors (“It’s natural to make mistakes”). Nor does introversion conflict with extroverted behaviors: “You have to be adaptive around other people. It would be weird to be the same kind of person on a date and with my friends at a football game!”

There are cognitive acquisitions that allow the older adolescent to overcome some of the liabilities of the previous period, when potentially opposing attributes were viewed as contradictory and as a cause of internal conflict. The general cognitive advances during this period involve the construction of higher-order abstractions that involve the meaningful intercoordination of single abstractions (see Case, 1985; Fischer, 1980; Fischer & Canfield, 1986). For example, the fact that one is both introverted and extroverted can be integrated through the construction of a higher-order abstraction that defines the self as “adaptive.” The observation that one is both depressed and cheerful or optimistic can be integrated under the personal rubric of “moody.” Similarly, being “flexible” can allow one to coordinate conscientiousness with the tendency to be lackadaisical. The higher-order concept of “ambivalence” integrates the desire to be independent yet still remain connected to parents. Moreover, “bittersweet” reflects a higher-order abstraction combining both excitement over going to college with sadness over leaving one’s parents. Such higher-order abstractions provide self-labels that bring meaning and therefore legitimacy to what formerly appeared to be troublesome contradictions within the self.

Neo-Piagetians such as Case (1985) and Fischer (1980) observe that developmental acquisitions at these higher levels typically require greater scaffolding by the social environment in the form of support, experiences, instruction, and so on in order for individuals to function at their optimal level. If these new skills are fostered, they will help the adolescent to integrate opposing attributes in a manner that does not produce conflict or distress. Thus, efforts to assist the adolescent in realizing that it is normal to display seemingly contradictory traits, and perhaps quite appropriate, may alleviate perceptions of conflict. Moreover, helping teenagers to provide higher-order labels that integrate opposing attributes (e.g., flexible, adaptive, moody, inconsistent) may avert some of the distress that was salient during middle adolescence. These suggestions derive from the observations of Fischer, Case, and others to the effect that these cognitive solutions will not necessarily emerge automatically with development. Nor will the potential benefits derived from movement to late adolescence and early adulthood necessarily accrue; that is, the levels described in this chapter represent a normative sequence of development. However, the age levels are somewhat arbitrary in that certain individuals may not attain a given level at the designated age period. Development may be delayed or even arrested if there is not sufficient support for the transition to a new level of conceptualization, particularly for the higher stages.

The assertion that the changing cognitive structures emerge—ideally—in late adolescence to early adulthood will allow for a potential reduction in the number of contradictory attributes identified in one's self-portrait, as well as diminished conflict, has found partial support in our own findings. For example, in one study (Harter & Monsour, 1992) in which adolescents described their attributes in four roles—with parents, with friends, with romantic others, and as a student—there was a dramatic rise in the number of opposites and conflicts identified at mid-adolescence, followed by a slight decline among older adolescents. Evidence that older adolescents become better able to consolidate or integrate seeming contradictions within the self-theory come from the comments they made in response to a follow-up interview. As one older adolescent explained, "Sometimes I am really happy, and sometimes I get depressed. I'm just a moody person." Another commented, "I can be talkative, and I can be quiet. I'm flexible, plus they complement each other. It's good to be both ways."

The tendency to *normalize* or find value in seeming inconsistency can also be observed in the comments of older adolescents, for example, "You wouldn't be the same person on a date as you are with your parents, and you shouldn't be. That would be weird." Another asserted, "It wouldn't be normal to act the same way with everyone. You act one way with your friends and a different way with your parents. That's the way it should be." Others made similar comments, for example, "It's good to be able to be different with different people in your life. You'd be pretty strange and also pretty boring if you weren't"; "You can be outgoing with friends and then shy on a date because you are just different with different people; you can't always be the same person and probably shouldn't be"; "There are situations where you are a good listener and others where you are talkative. It's good to be both." Thus, older adolescents come to the conclusion that it is desirable to be different across relational contexts, and in so doing, they would appear to be cultivating the stance that social psychologists (see Gergen, 1968; Mischel, 1973; Vallacher, 1980) identify as more the rule than the exception for adults.

The Role of the Socializing Environment

Recent evidence (see Harter et al., 1997) indicates that the ability to resolve potentially contradictory attributes may be more difficult for some role-pair combinations than for others, particularly for females. For example, as Figure 11.3 reveals, when all role pairs are combined, there is no decline in the number of opposing attributes identified

across roles. In fact, for older adolescent females, there is actually a further increase. The fact that six roles were included in the study generating the data in Figure 11.3 (compared to only four in the original Harter & Monsour, 1992, study) may have been partly responsible, as the inclusion of additional roles increased the probability that opposing attributes might be detected; that is, there were 15 possible role pairs that might contain contradictions, compared to only six role pairs in the original study. In increasing the number of roles, we also separated the reports of self-attributes with mother and with father (whereas in the earlier study, we merely inquired about self with parents).

The separation of self-attributes with each parent potentially enhances the likelihood that characteristics with each may contradict attributes in roles with peers. Examples generated by adolescent respondents in mid- to late adolescence included being short-tempered with mother versus a good listener in romantic relationships; respectful with father versus assertive with friends; and distant from father but attentive with a romantic interest. Adolescent bids for autonomy from parents (Cooper, Grotevant, & Condon, 1983; Hill & Holmbeck, 1986; Steinberg, 1990), coupled with the increasing importance of the peer group (Brown, 1990; Savin-Williams & Berndt, 1990), would lead to the expectation that attributes expressed with mother and father might well differ from those displayed with peers (namely, friends and romantic partners), leading to a greater potential for contradictions.

However, the separation of self with mother and self with father also creates the potential for attributes with mother to be in opposition to attributes with father. The potential for attributes with each parent to appear contradictory can be observed in the cameo, where the prototypical older adolescent feels much more mature with father than with mother. Moreover, such conflicts begin to be observed in midadolescence, where the prototypical teenager indicated that she was "close" with her mother but "distant" with her father, a difference that became problematic if they were all together, such as talking at dinner.

When the findings in Figure 11.3 are broken down by relationship pairs, opposing attributes and associated conflicts were most frequent for the combination of self with mother versus self with father, beginning in midadolescence and increasing in late adolescence, a pattern that we have since replicated in a subsequent study. Examples include being close with mother versus distant with father; stubborn with mother versus respectful with father; open with mother but not with father; at ease with mother but defensive with father; and hostile with mother but cheerful

with father. Moreover, such opposites between self with mother versus self with father, as well as associated conflict, increased dramatically for older girls in particular.

The fact that older female adolescents reported increasing contradiction, whereas male adolescents did not, suggests that cognitive-developmental explanations are incomplete. The separation of attributes with mother and with father, in particular, would appear to make it more difficult for certain adolescents to cognitively resolve or normalize the contradictions that are provoked by these roles, contradictions produced by the opposing attributes with mother versus father, as well as those attributes with each parent that contradict the characteristics that one displays with peers. Contradictions between self with parents and self with peers is more understandable, given developmental bids for autonomy. But why should adolescents (particularly adolescent females) report increasingly different characteristics with mother and father?

Here, we can only speculate. Family therapists observe that children and adolescents typically develop different relationships with each parent, which in turn may cause the salient attributes in each relationship to vary considerably. Contributing to these dynamics is the fact that each parent may have a different set of expectations about those characteristics that he or she values and therefore attempts to foster. First, the adolescent may become caught in a struggle between two parents who are encouraging and reinforcing different facets of his or her personality, provoking opposing attributes and resulting conflict. Second, both of these roles, self with mother and self with father, occur within the same general context, the family, whereas other multiple roles are not as likely to be called on simultaneously. These particular conditions may exacerbate the contradictions and conflicts that adolescents experience in their respective roles with mother versus father. These family dynamics appear to be relevant to the increase in across-role opposing attributes for female adolescents in particular, who may be more likely to be sensitive to the fact that they are behaving differently with mother versus father. As observed in the previous section on the period of midadolescence, females display more concern over relationship issues, which may make opposing attributes more salient. Adolescent females may also feel that to remain connected to both mother and father, it is important to be consistent across these relationships, a task that can be problematic for the reasons cited earlier.

Although the gender literature suggests that connectedness is more critical to females than to males (Chodorow, 1989; Eichenbaum & Orbach, 1993; Gilligan, 1982; Gilli-

gan, Lyons, & Hanmer, 1989; Jordan, 1991; J. B. Miller, 1986; Rubin, 1985), the adolescent literature reveals that it is important for teenagers of both genders to remain connected to parents in the process of individuation and the establishment of autonomy (Cooper et al., 1983; Hill & Holmbeck, 1986; Steinberg, 1990). As our prototypical subject reveals, although it is important to go to college where he or she can be more independent, it is also important to stay connected to parents.

Contextual factors such as the family, therefore, will conspire with cognitive development to impact the extent to which opposites and conflicts are experienced. Another example of the role of context can be observed in cross-cultural research by Kennedy (1994). Kennedy adapted our procedure in comparing the self-understanding of American and Korean youth. He finds that there are different age-related peaks in conflict among adolescents in the two cultures. Korean youth report increased conflict between opposing attributes in 10th and 12th grades, findings that he interprets in terms of the demands of the school context at those particular grade levels. In Korea, 10th grade is the 1st year of high school, and the new students are required to be deferential to the juniors and seniors, a relationship that many 10th-graders find oppressive. Kennedy argues that these demands exert a strain on the self-system and destabilize students' sense of self as they struggle to find a niche in the peer hierarchy of high school. During 12th grade, there are different demands, for example, intense preparation for the college entrance exams. This pressure leads to challenges in balancing the demands of academics, peer relationships, and family commitments, resulting in greater conflict.

Future research should attend to such contextual factors and attempt to assess the underlying processes more directly. To return to our own findings in this regard, it would be of interest to determine whether the conflict between self-attributes with mother versus father is more intense if the adolescent is living in a two-parent family where both mother and father are in the same household, or if the parents are divorced and living apart. One hypothesis is that living under the same roof with both parents makes it difficult to avoid conflict if different attributes in each relationship are demanded simultaneously. Alternatively, conflict may be exacerbated in the situation of divorce to the extent that in an acrimonious separation, each parent intensifies his or her differential expectations for the attributes they want the adolescent to display as part of a power struggle in which the adolescent becomes a pawn. Such processes would be intriguing to investigate.

Finally, with regard to developmental changes in the self, evidence from longitudinal studies reveals that self-esteem or global self-worth improves in later adolescence (see Engel, 1959; O'Malley & Bachman, 1983; Rosenberg, 1986; Simmons, Rosenberg, & Rosenberg, 1973). Several interpretations of these gains have been suggested (see Harter, 1990b; McCarthy & Hoge, 1982). Reductions in the discrepancy between one's ideal self and one's real self, between one's aspirations and one's successes, according to James's (1892) formulation, may be in part responsible. As the prototypical adolescent indicates, he or she has more self-respect now compared to a few years ago and observes, "I'm pretty much being the kind of person I want to be. I'm doing well at things that are important to me like getting good grades and being ethical." Gains in personal autonomy and freedom of choice may also play a role, in that the older adolescent may have more opportunity to select performance domains in which he or she is successful. Such freedom may also provide one with more opportunity to select those support groups that will provide the positive regard necessary to promote or enhance self-esteem, consistent with the looking-glass self formulation. Increased role-taking ability may also lead older teenagers to behave in more socially acceptable ways that enhance the evaluation of the self by others, such that the favorable attitudes of others toward the self are internalized as positive self-worth.

These others include parents. Although it has been common in treatments of adolescent development to suggest that the influence of peers increases, whereas the impact of parental opinion declines, findings do not support the latter contention. As our cameo subject indicates, "What my parents think about me is still important to how I feel about myself as a person." Our own findings reveal that the correlation between classmate approval and global self-esteem does increase during childhood and adolescence; however, the correlation between parental approval and global self-esteem, which is high in childhood, does not decline during adolescence (Harter, 1990b). The latter correlation does decline, however, during the college years among students who are away from home.

More specific evaluations of self-esteem continue to vary by relationship context (Harter et al., 1998) throughout the high school years as adolescents make finer distinctions (e.g., between their self-esteem with mother and with father). However, we did not anticipate the fact that for the vast majority of individuals, self-esteem in one particular relational domain is much more highly related to global self-esteem than is relational self-esteem in all other con-

texts. The specific domain occupying this position varies from adolescent to adolescent. For example, with our prototypical adolescent, self as student in the academic domain is most important ("Getting good grades is what is most important to me now"), and his or her self-esteem in that particular context is higher than in other domains. Thus, focusing on that particular context would appear to be very adaptive in that it should promote more positive feelings of global self-esteem.

Normative Liabilities during Late Adolescence

Many of the limitations of the preceding period of midadolescence would appear to be overcome as a result of changes during late adolescence. Attributes reflecting personal beliefs, values, and standards become more internalized, and the older adolescent would appear to have more opportunity to meet these standards, thereby leading to enhanced self-esteem. The focus on future selves also gives the older adolescent a sense of direction. A critical cognitive advance can be observed in the ability to construct higher-order abstractions that involve the meaningful integration of single abstractions that represent potential contradictions in the self-portrait (e.g., depressed and cheerful do not conflict because they are both part of being moody). The older adolescent can also resolve potentially contradictory attributes by asserting that he or she is flexible or adaptive, thereby subsuming apparent inconsistencies under more generalized abstractions about the self. Moreover, older adolescents are more likely to normalize potential contradictions, asserting that it is desirable to be different across relational contexts and that it would be weird or strange to be the same with different people.

Nevertheless, conflict between role-related attributes does not totally abate in later adolescence. Conflict will be more likely to occur if the new skills that allow for an integration of seeming contradictions are not fostered by the socializing environment. Furthermore, opposing attributes across particular role combinations, notably self with mother versus self with father, continue to be problematic in late adolescence, especially for girls. To the extent that one's mother and father elicit or reinforce opposing attributes, cognitive solutions for integrating seeming contradictions would appear to be more difficult to invoke.

Last, although the internalization of standards and opinions that the adolescent comes to own as personal choices and attitudes toward the self represents a developmental advance, there are liabilities associated with this process. As Rosenberg (1986) observes, the shift in the locus of self-knowledge from an external to an internal source can

introduce uncertainty. As long as major truths about the self derive from omniscient and omnipotent adults, there is little doubt about their veracity. However, when the locus of self-knowledge shifts inward and adolescents must rely on their own autonomous judgment and insight to reach conclusions about the self, then the sense of certainty can be compromised.

Pathological Self-Processes and Outcomes in Late Adolescence/Early Adulthood

Many of the pathological processes that have been described in the earlier periods of adolescence can be observed in late adolescence, albeit in a somewhat different form due to developmental advances. Preoccupation with impossible cultural standards of attractiveness looms even larger as the older adolescent anticipates emerging adulthood, making it even more critical to attain these standards to be socially acceptable and successful in the new adult world order (Harter, 1999). For females, failure to meet these standards can lead to more pathological processes, which may include eating disorders.

For example, in one study conducted in our laboratory by Danis (see Harter, 1999), two eating-disordered groups of women college students were identified, those with symptoms of anorexia and those with symptoms of bulimia. These two groups were compared to a control sample who did not display such symptoms. Both the anorexic and the bulimic group reported significantly higher scores on the importance of appearance, toward the very top of the 4-point scale, compared to the normative sample. They each reported extremely low scores with regard to their evaluation of their physical appearance, creating a large discrepancy, namely, importance scores vastly higher than perceived appearance scores. This discrepancy clearly predicted very low self-esteem scores for the two eating-disordered groups compared to the normal sample. These low self-esteem scores, in turn, were highly predictive of extremely high levels of self-reported depression.

Of particular interest were the findings that although both eating-disordered groups reported this negative constellation of symptoms, those in the bulimic group were more at risk given the lowest ratings of perceived physical appearance, self-esteem, and depression. Danis interpreted this difference between the two eating-disordered groups in terms of perceptions of control. She argued that those with symptoms of anorexia were objectively thinner, leading them to possibly feel more successful in terms of their weight control. The bulimics, who by definition binge and purge, were interpreted to be less in control; moreover,

on average, this group was heavier. That said, those with anorexia are more at risk for malnourishment that can affect bone development, brain development, and body development in general, and in the extreme, they are at risk for death. Those with bulimic symptoms are also at risk for a variety of physical symptoms, including damage to the mouth and esophagus and other compromising physical growth symptoms. Of course, there are also numerous psychological symptoms, including disruptions within the family, compromised academic achievement, and impaired social functioning.

In another study on this same topic (Kiang & Harter, 2004), we developed an instrument to assess the extent to which young college-age women bought into cultural messages about the link between meeting cultural standards of attractiveness and outcomes such as popularity, approval, love, and economic and job success. The findings revealed that those who strongly endorsed these links reported markedly lower self-esteem, depression, and eating-disordered symptoms. Young adults at this period are *less* likely to report the vacillations that are observed during middle adolescence, marking their perceptions of negativity as more stable because they have become entrenched in these views as a core belief system.

Male adolescents are clearly at continued risk for violence, particularly the type of violence that emanates from peer rejection and humiliation. Chronic rejection and humiliation are likely culprits for violent ideation (Harter, in press) and for violent action, as in the case of the school shooters. Unlike the impulsive acts of the school shooters in middle adolescence, the acts of Eric Harris and Dylan Kleibold from Columbine, who were older teens, were far more *planful*. For over a year, they had developed their strategies, some of which were revealed in Harris's written manifesto. Although this is speculative, in examining the media accounts of the 11 high-profile school shooting cases, it would appear that the dynamics may be different from what we normally consider to be delinquent, conduct-disordered behavior that had come to the attention of teachers, school officials, school psychologists, peers, and parents. In most of these cases, there were few warning signs with regard to the male shooters having been in trouble with the law, having been identified as troublemakers in the school, having clinical diagnoses, or being placed in special classes for students with a penchant for acting out. As noted earlier (Harter & McCarley, 2004), we found that 33% of those reporting to us that they had serious thoughts of harming others who humiliated them went undetected by their classroom teachers who were given parallel rating

forms. Thus, there is a need to discriminate the form of violence that has recently emerged from previous acts that have been committed by known delinquents and conduct-disordered youth who have come to the attention of school and mental health professionals and who commit different types of crimes, for example, drive-by shootings to target one individual versus the random shooting of as many classmates as possible. The dynamics appear to be different and deserve our attention.

The construction of multiple selves, though a normative process, can also have pathological implications. It was pointed out in the section on middle adolescence that the effects of abuse can lead to dissociative symptoms that prevent one's multiple selves from being integrated. In the severest cases, this can lead to Dissociative Identity Disorder (what used to be termed Multiple Personality Disorder). Abuse has also been found to impact the valence (positive or negative) of those attributes judged to be one's core self (versus more peripheral attributes). Normatively, we have found that when asked to rate the attributes across multiple relational contexts with regard to whether they are central core characteristics or more peripheral, less important attributes that define the self, normative samples of older adolescents will define their most important attributes as *positive* and assign their more negative characteristics to the periphery of the self, that is, as less important attributes (Harter & Monsour, 1992). This self-protective strategy has been defined normatively as "ben-effectance" by Greenwald (1980), or seeing one's positive attributes as central to the self and one's negative attributes as more peripheral.

Our colleagues Fischer and Ayoub (1994) employed our multiple selves procedure with an inpatient sample of seriously abused older adolescent girls, finding just the opposite pattern. Compared to a normative sample, the abused patients identified *negative* attributes as their core self, relegating what few positive characteristics they could identify as peripheral. Herein we can detect another deleterious effect of abuse on self-processes leading to potential pathological outcomes; these require clinical intervention that we would hope can restore a more positive balance of self-perceptions.

CONCLUSIONS AND FUTURE DIRECTIONS

At the outset, I set forth a framework in which I first applauded the many efforts of those in the field who have tried to give dignity and depth to the field of developmental psychopathology, who have attempted to carve out a dis-

tinct subdiscipline that clearly warrants our attention. Much has been learned about the developmental trajectories of particular disorders in childhood and adolescence, focusing on individual differences and multiple pathways to a given disorder. This has yielded a vast array of findings that are not only interesting for their scientific merit but have greatly aided clinicians in their treatment of the various pathologies of childhood and adolescence.

In my reading of this literature, a subset of publications in the larger field of clinical psychology, it seems that often there has been a top-down approach in which diagnostic criteria initially established for adults have been applied to children and adolescents, with some modifications for the age of the individual. Yet the approach, including in the forthcoming *DSM-V*, still involves lists and categories of symptoms specifying criteria (e.g., numbers of symptoms in each category) to arrive at a diagnosis. With the exception of certain age-related criteria, there has been little emphasis on process models of pathology or an appreciation for what we know about normative sequences of development as a backdrop for our understanding of psychopathology.

Basic empirical research on the various disorders of childhood and adolescence has devoted more attention to the processes and dynamics underlying given disorders. Clearly, much of the exciting longitudinal work addresses development in an important sense, namely, how these disorders unfold over time. To what extent can we predict an individual's future with regard to the course of a given form of psychopathology? These are critical endeavors contributing to our understanding of disordered behaviors.

That said, however, as I suggested in the introduction, we could put more "development" into the discipline of developmental psychopathology. The fields of developmental psychology and clinical psychology have for too long been segregated. Elsewhere I have commented on the fact that there has been too much segregation between the fields of traditional social psychology, as applied to adults, and developmental psychology. Often, top-down models of adult social psychological phenomena are glibly applied to children, employing the same paradigms and models as well as watered-down versions of instruments that primarily attend to vocabulary level, not changes that might be sensitive to the developmental level of the child or adolescent.

What would it mean to put more "development" into developmental psychopathology? At one level, the direction that the field has taken in the past 2 decades may seem to have made this task increasingly difficult. We have engaged in theoretical homicide. We have shot down our early heroes: Piaget, Freud, Vygotsky, Werner, and Erikson. We

have been critical of their grand formulations, the omnibus theories that we now view as too vague and imprecise; we have struggled with the distinction between scope and precision, seemingly opting for the latter. Now we scramble to create minitheories of our own pet constructs for our own given age level or population, minitheories that will pepper the publication landscape of our ever-so-fragmented proliferation of journals that speak primarily to our specialty. Where are the developmental compasses, be they theoretical, methodological, or empirical, that could guide us in understanding psychopathological conditions that are very real in the lives of children and adolescents?

There may be a middle ground where we can adopt the developmental spirit of our forefathers who illuminated fascinating developmental sequences, albeit somewhat broad, vague, imprecise, cumbersome, and therefore not so amenable to rigorous documentation. By that I mean that we can take a particular construct of interest, narrowing our scope but addressing precision in terms of identifying the developmental sequence and the underlying processes that govern the unfolding of that construct.

My goal for this chapter was to adopt such an approach and to apply it to the self-system. We know that there are disorders that involve the self. Might not an initial understanding of the normative developmental progression of self-understanding aid us in thinking about such disorders? Yet we need to go far beyond the documentation of such normative sequences. Thus, I have attempted to take an expanded approach, first identifying three periods of childhood and three periods of adolescence where we can identify clear changes with regard to self-development. Within each of these six periods, I have identified three levels of analysis: normative-developmental descriptions of how self-processes change; and normative liabilities that I have argued are just that, bumps in the psychological road that will be leveled out, developmentally graded, as it were, through the help of naturally occurring neurological development but even more strongly by the attentive and thoughtful scaffolding of socializing agents in the lives of children and adolescents. With regard to the latter, there are those who have emphasize the importance of such scaffolding (Fischer, Rogoff, and others) who are making powerful contributions to our understanding of development. Finally, I made the distinction between normative liabilities and more severe pathological self processes.

We could adopt such an approach in domains other than the self that are relevant to developmental psychopathology, for example, aggression, school violence, ADHD, depression, emotionality, abuse and trauma, Autism, and neurological conditions. Obviously, some of this work has been

conducted by individual investigators, and very effectively. However, we lack such an approach as an overarching model for how to understand developmental psychopathology. Moreover, we do not employ such a model in most of our training programs for graduate students. A truly developmental perspective would force us to think differently about how and why symptoms in a family of disorders may differ or, conversely, appear to be similar over time.

I would modestly suggest that perhaps the most valuable contribution of the framework that I have attempted to articulate is the distinction between normative developmental liabilities and truly pathological processes. An understanding of this distinction could be invaluable for clinicians, giving them guidance about how not to overpathologize. Moreover, such an understanding could greatly enhance our ability to comfort concerned parents of children and adolescents who may come to our clinics, by emphasizing that certain behaviors that appear pathological are normal manifestations of development, albeit sometimes painful perturbations for the child and family alike. Moreover, we can offer comfort to the distressed child or adolescent client, emphasizing that many of these normative liabilities are just that, normal, common experiences that are shared with others their age. Obviously, we also need to be clear on the distinction between such normative liabilities and truly pathological processes that require a different set of clinical interventions. It is hoped that this type of approach could bring developmental researchers and clinicians committed to an understanding of developmental psychopathology closer together, for the good of each of us, the clients and families we serve as well as the field at large.

It is a measure of the persuasiveness of the cumulative body of research on children's peer relationships that it has become trite to claim that peer experiences significantly shape development and the development of psychopathology. Few contemporary psychologists—and few laypersons, for that matter—doubt that children come to know themselves at least partly from how they are treated by peers; that relationships with peers provide rich opportunities for learning cooperation, gaining support, or developing interpersonal skills; or that persistent difficulties in getting along with childhood peers are likely to portend difficulties with others later in life and, in the extreme, clinically significant behavioral and affective disorders.

This has not always been the case. When we introduced this chapter a decade ago, we noted its timeliness by observing that it coincided with what appeared to be a nascent and important shift away from “regarded variations in children's experiences with peers as derivative of broader achievements or failings of personality development and without developmental consequences of their own” (Parker, Rubin, Price, & DeRosier, 1995, p. 96).

Even as the developmental significance of peer experiences has become less disputable, understanding the roots and consequences of peer experiences has grown more complex and arguably less tractable. To begin with, it is more difficult now than a decade ago to understand which children

are experiencing difficulties with their peer relationships. The past decade has witnessed unprecedented advances in the development and refinement of methods for studying adjustment with peers (e.g., see Bukowski & Cillessen, 1998), so much so that space considerations now prevent us from treating assessment issues as comprehensively as we did a decade ago. If advances in assessments have made unprecedented progress, why is it so much harder today than a decade ago to represent children's peer difficulties?

The paradox lies in the growing appreciation for the great diversity of ways in which success or failure with peers may be played out in life and represented in assessments. A decade ago, the effort to conceptualize and assess individual differences in children's adjustment with peers was dominated by a focus on sociometric status in school classrooms and grades. A watershed in interest in peer group acceptance and rejection may have been reached in the early 1990s beginning with the publication of a landmark volume edited by Asher and Coie (1990), but research on this construct remains a dominate focus today (e.g., Cillessen & Bukowski, 2000; Furman, 1996).

Today, evidence has slowly mounted to suggest that gauging adjustment with peers is not as simple as understanding the degree to which individuals are accepted or rejected by significant peer groups. Instead, steady progress has been made, especially recently, in understanding that other dimensions of adjustment also exist and carry weight. For example, researchers have suggested that being well liked or popular in a peer group may be something altogether distinct from being perceived by other children as popular (Lease, Kennedy, & Axelrod, 2002; Lease, Musgrove, & Axelrod, 2002). Some children are perceived by peers to be popular, although more objective assessments indicate that they are not. When compared to children who are well liked by others, children perceived to be popular appear to have some personal characteristics that are more usually associated with rejection (Buskirk, Rubin, Burgess, Booth-LaForce, & Rose-Krasnor, 2004; LaFontana & Cillessen, 1999; Parkhurst & Hopmeyer, 1998). Another element of complication derives from recent research on friendship. Friendship and acceptance are connected in important ways (e.g., George & Hartmann, 1996; Newcomb, Bukowski, & Bagwell, 1999; Sabongui, Bukowski, & Newcomb, 1998). However, friendships appear to play different functions in children's development than does group acceptance; moreover, group acceptance neither guarantees nor precludes successful friendship experiences (Asher, Parker, & Walker, 1996; Bigelow, Tesson, & Lewko, 1996; Brendgen, Little, & Krappmann, 2000; Hoza, Molina, Bukowski, & Sippola,

1995; Ladd, Kochenderfer, & Coleman, 1997; Parker, Saxon, Asher, & Kovacs, 1999). Yet another element of complication is the recent discovery that children develop enemies somewhat independently of their group standing and success with friends (Abecassis, 2003; Parker & Gamm, 2003). We have only a beginning understanding of the developmental significance of such mutual antipathies, but we can conclude safely at this early stage that the presence of these relationships challenges our understanding of social competence and what it means to be successful with age-mates (Hodges & Card, 2003).

An additional challenge stems from recent recognition that many ostensibly positive peer experiences may also encourage maladjustment. For example, decades of research have documented the social difficulties of aggressive children, but new evidence suggests that, in specific circumstances, individuals who are "mean" can be attractive to others (Farmer, Estell, Bishop, O'Neil, & Cairns, 2003; Hawley, 2005; Rodkin, Farmer, Pearl, & Van Acker, 2000). Conversely, while appropriately celebrated for their positive influence on children's satisfaction and development, recent evidence suggests that friendships can also be a source of tension, and friends can deeply disappoint their partners. Children often value their friends because they provide opportunities for emotional support and self-disclosure, and researchers have typically assumed that self-disclosure in friendship indicates healthy functioning. However, some friendships are characterized by aggressive behavior (e.g., Crick & Nelson, 2002; Poulin & Boivin, 2000) and other recent evidence suggests that children who discuss deviance in their disclosures with friends are at increased risk for deviance themselves (e.g., Brendgen, Vitaro, & Bukowski, 2000; Dishion, Andrews, & Crosby, 1995; Dishion, Spracklen, Andrews, & Patterson, 1996; Keenan, Loeber, Zhang, Stouthamer-Loeber, & Van Kammen, 1995; Poulin, Dishion, & Haas, 1999; Urberg, Degirmencioglu, & Pilgrim, 1997) and discussions of personal problems among friends that become preoccupying can increase rather than decrease children's risk of internalizing disorders (Rose, 2002). Likewise, having multiple friends is usually and rightly considered a positive sign of adjustment with peers. Yet, in specific friendships, feelings of jealousy can arise in one member if their friend's interest in, or activities with, an outsider highlights their own shortcomings in important areas or is perceived as an infringement on the quality or sovereignty of the relationship. There is evidence that feelings of jealousy, an emotional experience born from closeness, can damage children's intrapersonal adjustment and result in negative behavior

(Parker, Low, Walker, & Gamm, 2005). Romantic relationships, too, can be characterized by intense conflict and feelings of insecurity, exploitation, and sadness (Joyner & Udry, 2000; Richards, Crowe, Larson, & Swarr, 1998). The double-edged nature of these bonds, as it were, make it more risky now than a decade ago to make assumptions about the protective factors associated with various positive indicators of adjustment with peers or the risks associated with markers that appeared uniformly negative.

Finally, a discernable and natural progression has taken place in the balance of simple descriptive versus process-oriented studies in this area. This is perhaps most readily apparent in the evolution of research on children's rejection by the peer group. When closing our chapter a decade ago, we lamented that insufficient attention had been paid to the processes underlying sociometric classification and categorization in the study of peer rejection. Instead, researchers appeared content to conduct study after study comparing rejected children to other children on variable after variable. We noted (Parker et al., 1995, p. 144): "Few data exist, for example, on the frequency with which peer rejected children are excluded from playground games, experience teasing and taunts, or are otherwise victimized by other children." Our concern at the time was that sociometric status researchers were elevating the traditional categories of popular, rejected, neglected, and controversial to social address variables (Bronfenbrenner & Crouter, 1983) and might be losing sight of whether and how they were grounded in the day-to-day experiences of children. Without such an understanding, little progress seemed possible in understanding the processes by which sociometric status groups arise and how they influence individuals, dyads, and groups.

The circumstances today are different. Although the classification and comparison of children of differing sociometric status remains an important field of inquiry, many of these same investigators have begun to study bullied and victimized children (see Juvonen & Graham, 2001; Ladd & Burgess, 1999; Rodkin & Hodges, 2003). Peer rejection and peer victimization are distinct constructs but overlap in important ways. However, by formulating their questions in terms of a specific type of interpersonal process (peer victimization and bullying), this newer tradition requires a smaller leap from description to process. However, as Bronfenbrenner and Crouter (1983) also pointed out, process-oriented accounts of social experience seldom provide the same satisfying generalizations about individuals that social address models appear to. Instead, they demand close attention to the moderating effects of person- and context-level variables. Thus, as our understanding of

peer victimization has grown, it has become apparent that the developmental significance of this experience is not simple (Boulton, Trueman, Chau, Whitehand, & Amatya, 1999; Graham & Juvonen, 2001; Hanish & Guerra, 2004; Hodges, Boivin, Vitaro, & Bukowski, 1999; Juvonen & Graham, 2001; Kochenderfer & Ladd, 1997; Olweus, 1993; Salmivalli, Huttunen, & Lagerspetz, 1997; Salmivalli & Voeten, 2004). Whether and in what way victimization affects children appears to depend on the context in which it occurs. For example, is the child a member of a numerically larger subgroup or perhaps a member of a minority ethnic group? Is aggression otherwise normative for the group in which victimization occurred? Is the perpetrator a dominant or submissive individual in terms of status in the relevant peer group? What are children's attributions for why a particular aggressive act occurs? Is the victimized child also a perpetrator at other times? What are the child's social resources (e.g., Does the child have friends)? Is the perpetrator or the victim socially skilled? What about the self-esteem and gender of the perpetrator or victim? Was the abuse of a physical, verbal, direct, or indirect nature? Our task has become complicated indeed.

ORGANIZATION OF THE CHAPTER

Normative developmental trends in children's peer experiences provide a foundation for understanding peer relationships from a developmental psychopathology perspective. Thus, in the first section, we trace peer experiences and relationships from their building blocks in infancy and early childhood through their advances in adolescence when increasingly stable and intimate friendships are formed and romantic relationships take shape.

Following this, we discuss the major theoretical frameworks that have guided thinking and research on the importance and impact of peer relationships. The study of children's adjustment with peers sits at the juncture of a number of different scientific frameworks, but is the central focus of none. As such, we review how several theoretical perspectives have been insightful and provocative in particular respects. As will be apparent, in some formulations, peer experiences are suggested to contribute to development in ways that are unique from children's experiences with adults; in others, peer experiences offer an important countervailing influence to the influence of adults; in still others, peer experiences and adult influences are seen to share many similarities. Further, in

some cases, the implications of unsuccessful adjustment with peers are drawn out explicitly, though in others they are only implied.

In the next section, we illustrate some of the many dimensions along which children's peer experiences may differ. This discussion emphasizes that even within the broad domains of friendship and peer acceptance, the potential for individual differences in peer experiences are numerous.

In the following sections, we tackle the implications of problematic peer relationships. The possibility that children with problematic peer relationships are at increased risk for later adjustment difficulties has attracted clinicians, epidemiologists, and others to the study of peer adjustment in the hopes of improving the early identification and prevention of adolescent and adult mental health disturbances. Studies in this area form an important interface between the sciences of developmental psychology, child clinical psychology, and developmental psychopathology. Our review turns initially to the question of the interface of peer relationship difficulties and psychological disorders. Next, relying heavily on the principles of developmental psychopathology, we take a longitudinal perspective and discuss developmental pathways and transactional models to illuminate the links between early peer problems and maladjustment later in life.

Following this, we review research pertaining to reciprocal influences between children and their peers to support a model of the processes underlying peer maladjustment. This model specifies the reciprocal roles of child social cognition and behavior and peer appraisals and responses in the unfolding of peer adjustment or maladjustment, with attention to the emerging understanding of emotion in this process.

Finally, we use child social anxiety to illustrate how the principles of developmental psychopathology may guide our understanding of peer maladjustment and end our chapter with some discussion of directions for future research.

DEVELOPMENTAL TRENDS IN CHILDREN'S PEER INTERACTION AND RELATIONSHIPS

As with any class of complex behavior, understanding children's behavior with peers requires an appreciation of the child's developmental status and the dynamic organization of the behavior over time (Cairns, 1979; Cicchetti, 1990). Although the argument that one must consider development when considering the meaning of behavior for actors and recipients seems obvious, in fact, the study of social development has been decidedly nondevelopmental for most of

its history (Cairns, 1979; Sroufe & Jacobvitz, 1989). Moreover, an understanding of the major mileposts and transformations in peer experiences that occur with age is necessary to recognize and understand individual patterns of adaptation and maladaptation with peers (Cicchetti, 1993; Selman & Schultz, 1990; Sroufe & Rutter, 1984). Deviations, delays, or distortions in the development of peer relationships derive their meaning only through consideration of the timing, nature, and course of peer experiences in the average or expectable instance.

In this section, we examine children's peer experiences and relationships from infancy through adolescence. Our concern is with the general developmental changes in the quantity, quality, and context of children's peer contacts and relationships. These normative patterns then provide a framework for considering the role of peer experiences in development and the considerable variation existing among individual children in the success of their adjustment with peers.

Infancy and Early Childhood

Infants have obvious motor, cognitive, and verbal limitations that restrict their capabilities for, and interest in, peer interaction in the first 3 to 4 months of life. However, smiling, vocalizing, and reaching toward peers appears toward the end of the first half year of life and infants begin to coordinate their interactions with other children shortly thereafter (D. F. Hay, Pederson, & Nash, 1982; Vandell, Wilson, & Buchanan, 1980). These initial exchanges are short, two-turn reciprocal chains, typically involving an infant exhibiting a social behavior, such as pointing or vocalizing toward another baby, and the other baby's responding in kind. Agonistic acts and object-centered activities are rare at this age. Interestingly, even at these early ages, considerable variability in interactive behavior is evident; some infants repeatedly direct social acts toward other children, whereas other infants do so very rarely (National Institute of Child Health and Human Development-Early Child Care Research Network, 2001).

Growing Reciprocities

The social exchanges of older infants and toddlers are more predictable, complex, coordinated, and lengthier (Dishion, Andrews, & Crosby, 1995; Eckerman, 1993; Eckerman & Didow, 1996; Eckerman & Peterman, 2001; Ross, 1982). Around the time of the first birthday, children become capable of shared activity with peers (Howes, 1996). Initially, these activities center primarily on ob-

jects (Mueller & Brenner, 1977). Divisive struggles over objects are common, but so, too, are more integrative exchanges, such as imitation of other infants' behaviors toward objects, particularly as children reach the age of 20 to 24 months. An age-mate makes an ideal model of what to do with objects, and toddlers' imitations of one another and other exchanges around objects mark the emergence of the earliest forms of cooperative and coordinated activity (Eckerman & Peterman, 2001).

The object-centeredness of children's peer interchanges declines from the beginning to the end of the 2nd year of life (Mueller & Brenner, 1977). Mueller and Silverman (1989) suggest that this signals a subtle but significant transformation in peer relationships in that it marks a transition from a focus on activities to a focus on the social relationship itself.

The period from 16 or 18 months to about 3 years is marked by social interaction that is increasing socially oriented and more truly complementary and coordinated (e.g., Eckerman & Peterman, 2001; Ross, 1982). The consolidation of locomotion and, especially, the emergence of the ability to communicate meaning through language, play significant roles in this transformation (e.g., Dunn, 1988; Howes, 1992). It is during this period that lighthearted and playful games can first be identified in toddlers' interactive exchanges (Ross, 1982). Eckerman and Peterman (2001) outline a developmental progression of toddlers' cooperative and coordinated action over this period. In their model, at around 16 months of age, toddlers participate in ritualized coordinated action, usually with familiar and older peers. From 20 to 24 months, nonritualized coordinated action with peers emerges, primarily through nonverbal imitative acts. Nonverbal imitative activity during this period promotes shared understanding of social interaction, which sets the stage for verbal means of achieving coordinated action. Finally, from 28 to 32 months, toddlers integrate verbal and nonverbal means of achieving coordinated action.

Fantasy Play

Social pretend play permits young children to successfully work through fears and other emotional issues (Parker & Gottman, 1989; Rubin, Fein, & Vandenberg, 1983; Sawyer, 1997). In addition, even very young children use pretend play to establish and maintain social relationships with peers (Eckerman, 1996; Gottman, 1983). Howes (1992) describes the gradually unfolding sequence that takes place over the span from 16 months to 3 years in the growth of children's skills at communicating meaning in the context of social pretense. At the beginning of this period, chil-

dren's play and games have a complementary and reciprocal structure (e.g., run-chase). Thus, their play is built on familiar and well-learned scripts or routines, permitting the children to play cooperatively with little need to communicate meaning. Social pretense at this point consists of little more than one child's imitation of the isolated pretense acts of another.

As language and symbolic capacity matures, however, social pretense undergoes regular, sequential changes. From 16 to 20 months, children's pretense becomes more abstract and distant from their actions. Children will not only match or imitate the pretend acts of other children but also attempt to recruit the partner to join their pretend play. These efforts are not routinely successful, but it is clear that children are beginning to understand that nonliteral meanings can be shared by partners.

From 21 to 24 months, children engage in similar pretend actions in the context of broader joint activity. Attempts to recruit others into pretense are more frequent and more successful. Although children organize materials for sociodramatic play, there is little or no joint organization of the pretend play itself. Scripted joint play emerges from 25 to 30 months, and the assignment of social roles in play (e.g., doctor, mother, father, police officer) emerges shortly thereafter, from 31 to 36 months. At this point, children understand that nonliteral meaning can be shared and they can communicate these meanings effectively during pretense with partners.

Early Friendships

The formation of specific friendships begins to be observed during the period from 18 to 36 months (Schneider, 2000). These friendships are indexed by mutual interaction preference, shared affect, scripted regularities in play, and differentially sophisticated play between peers (see Howes, 1996). Indeed, the percentage of children at these ages without friends is very small, at least among children in child care settings (Howes, 1983, 1988).

Because toddlers' concepts of a friend and friendship are limited (Selman, 1980), it is sometimes assumed that these early friendships are of marginal importance to children of this age. However, children with friends acquire social skills as a result of their participation in these relationships, especially if these relationships are maintained over time (Howes, 1996). Howes and Phillipsen (1998) reported that the complexity of children's social play during the toddler years predicted increased prosocial behavior and decreased social withdrawal during the preschool years, as well as decreased social withdrawal and aggression at 9 years of age. Moreover, toddlers regularly and

spontaneously discuss their friendship interactions with their parents at home, suggesting the salience of these relationships to even very young children (Krawczyk, 1985). Howes and Phillipsen (1992) found that 80% of friendships among toddlers who remained in the same child care setting lasted for 3 years. Nevertheless, friendships at this age are less stable than friendships formed after 3 years of age (see Schneider, 2000).

Mileposts of the Preschool Years

Peer interaction after the 3rd year and over the course of the remaining years preceding formal schooling continues to change in frequency and quality (Dunn, 1993). Children direct increasing amounts of attention to peers, and spend increasing amounts of time with peers, especially if they are enrolled in child care settings (Hartup, 1983; Schindler, Moely, & Frank, 1987).

Conflict

As might be expected from the increased contact and interest, conflict between age-mates increases in frequency and intensity over this period (D. Chen, Fein, & Tam, 2001; Vaughn, Vollenwieder, Bost, Azria-Evans, & Snider, 2003). In comparison to older children, preschoolers' conflicts are more likely to involve struggles over objects (Killen, 1991). Object struggles are not strictly pragmatic disputes, however, and probably involve disputes over moral issues and elements of social control as well (see D. F. Hay & Ross, 1982; Killen, 1991). For example, disputes over objects may arise from the demands on children to protect their interactive space (Corsaro, 1985). According to Corsaro, preschoolers' social interaction is especially fragile, in that intrusions by other peers can lead interactive episodes to terminate quickly without formal marking or opportunity for negotiation. Realization of this fact leads children to resist others' attempts to join in play, sometimes through claims and counterclaims of friendship. Regardless of its source, conflict exchanges during the preschool years may provide important opportunities for social-cognitive development and learning to manage conflict (Shantz & Hartup, 1992; Vaughn et al., 2003). Indeed, Vaughn et al. found that about one-third of preschool children with high observed social competence were also high on observational ratings of both dominance and prosocial behavior.

Overall, however, the proportion of conflict or aggressive interactions to friendly interaction declines across the preschool period as increasing language, self-regulation, and social-cognitive capacities allow children to resolve conflicts of interest in more prosocial ways (Coie & Dodge,

1998; Hartup, Laursen, Stewart, & Eastenson, 1988; D. F. Hay, Castle, & Davies, 2000). Conversely, prosocial behavior (e.g., helping, sharing, empathy) increases from the toddler years to the early preschool years (e.g., Eisenberg & Fabes, 1998; D. F. Hay, Castle, Davies, Demetriou, & Stimson, 1999) and is linked with peer acceptance during this period (e.g., Bierman & Erath, in press).

Play

Children's play also increases in social complexity during the preschool period; the most notable changes occur with respect to sociodramatic play, which increases notably over this period (Goncu, Patt, & Kouba, 2002; Rubin et al., 1983; Sawyer, 1997). Howes, Matheson, and Wu (1992) explored the role of complex social pretend play, which consisted not only of pretend play with defined roles (i.e., social pretend play), but also of meta-communication about pretend play (e.g., explicitly assigning roles, proposing a play script, prompting the other child). Complex social pretend play began to emerge around 36 months and increased through 60 months.

The skills of communicating meaning in social pretense are largely mastered by 3 years of age; thus, preschoolers' spontaneous social pretense is more likely to serve broader developmental functions (Howes & Phillipsen, 1998). Spontaneous fantasy play is especially critical to the establishment and maintenance of friendships in preschool (see Corsaro, 1985; Gottman & Parkhurst, 1980; Howes, 1992; Parker & Gottman, 1989). In addition, it provides preschool children with a vehicle for working through major concerns and fears (see Corsaro, 1985; Howes, 1992; Kramer & Gottman, 1992; Parker & Gottman, 1989). Not surprisingly, then, spontaneous pretend play during the preschool ages, especially between best friends, is more frequent and elaborate than at any other point in development (e.g., Corsaro, 1985; Forbes, Katz, & Paul, 1986; Howes, 1992).

Gender Differentiation

Normative gender differences in peer interaction also begin to emerge during the preschool years. Around the age of 3, children begin to show a strong preference for interacting with same-sex peers (Fabes, Martin, & Hanish, 2003; Maccoby, 1998; Powlishta, Serbin, & Moller, 1993). Although play is the primary form of social interaction for both sexes during early childhood (Maccoby, 1998), the type of play typical among groups of boys and girls shows distinctive features. For example, beginning in preschool, boys more often choose to interact with peers in larger groups that emphasize competition, hero and rescue themes, and rough-

and-tumble play, whereas girls more often play in smaller groups and emphasize conversation, cooperation, and relationship themes (Benenson, Apostoleris, & Parnass, 1997; Maccoby, 1998). Boys also display higher levels of activity, aggression, and positive emotionality, whereas girls engage in more frequent play in the proximity of adults (Fabes et al., 2003; Martin & Fabes, 2001). Interestingly, sex-differentiated play appears to be amplified by exposure to same-sex peers during the preschool years (Martin & Fabes, 2001), perhaps because both boys and girls make more positive overtures and responses to same-sex peers and to play behavior consistent with the preferences of their own sex (Fagot, 1985; Maccoby, 1998).

Developments in Later Childhood

The period of middle to late childhood, covering roughly the period from 6 years to 11 or 12 years, is characterized by a great deal of change and growth in interpersonal skills and in the context and quality of children's peer relationships.

Diversity and Differentiation

Positive peer experiences and friendships in preschool contribute to a smoother and more positive transition to formal schooling (Ladd, Kochenderfer, & Coleman, 1996). However, entry into formal schooling in turn greatly transforms peer experiences by increasing the size of the sphere of children's peer contacts. In addition, children's involvement in extracurricular and other forms of youth sports during middle childhood provides opportunities to develop friendships and affiliations outside of school. In fact, descriptive research suggests that the possibility of positive peer experiences is an important motive that attracts youth to organized sports activities (see M. R. Weiss & Smith, 1999; M. R. Weiss, Smith, & Theebom, 1996).

However, in addition to an increase in the number of available peers, children entering middle and later childhood are likely to encounter unprecedented variability in the ascribed (e.g., sex, race, ethnicity) characteristics and personalities of their peers, especially in school contexts. These differences contribute to discernible hierarchies of power and popularity (McHale, Dariotis, & Kauh, 2003), to salient similarities among playmates or friends (e.g., Kupersmidt, DeRosier, & Patterson, 1995; Newcomb et al., 1999), and to groups that are rigidly segregated along various lines (e.g., Abrams, Rutland, & Cameron, 2003; Horn, 2003).

Sex segregation is the most noticeable. The earlier trend toward a sex-segregated friendship group intensifies during this period, such that peer interactions and close

friendships occur almost exclusively with same-sex peers during middle childhood (D. M. Kovacs, Parker, & Hoffman, 1996; Sroufe, Bennett, Englund, & Urban, 1993). Indeed, at this age children who buck this imperative and have friendships primarily with members of the opposite sex tend to be children who are less well-liked by peers, less socially skilled, and more aggressive than children who form primarily same-sex friendships (D. M. Kovacs et al., 1996).

However, sex is not the only social category that divides children's groups beginning in early childhood. Children's recognition of race and ethnic differences also begins in the preschool period (e.g., Aboud, 1988). Preschoolers' sorting and labeling of others based on race or ethnicity is neither as accurate nor as comprehensive as it will become in middle childhood, however. Further, it is largely not until the middle childhood years that children begin to hold negative views about the categories to which they do not belong (Killen, Lee-Kim, McGlothlin, Stangor, 2002; Powlishta, Serbin, Doyle, & White, 1994). The rapidity with which children recognize and use social categories leaves an impression of a broad, qualitative, and domain-general developmental change in reasoning. However, recent research suggests that this is an oversimplification (Killen & Stangor, 2001; Killen, Stangor, Horn, & Sechrist, 2004). Children who are prejudiced in one domain (e.g., toward the opposite sex) are not necessarily prejudiced in other domains (e.g., toward another race) and evidence suggests that the recognition, use, and abuse of social categories develops from a complex interplay of environmental support, attitudes toward others, and a growing self-understanding (Liben & Bigler, 2002; Powlishta et al., 1994). Moreover, after a period of initial intensification, prejudicial attitudes decline across later childhood (Powlishta et al., 1994). Further, children show important developmental changes in their judgments of in-group and out-group members from age 5 years to 16 years (Abrams et al., 2003). In particular, with age, children attend not solely to a target individual's social category or group membership status, but also to the extent to which his or her personal characteristics conform versus deviate from those typical of the category. For example, children of all ages show bias in favor of in-group members over out-group members. With age, however, children become sensitive to differences among members within (versus between) groups—in both their in-groups and out-groups (Killen, Lee-Kim, et al., 2002). Among older children, then, typical in- and out-group biases can be erased or even reversed in the right circumstances. For example, older children during this period, but not younger children, show evidence of

sensitivity to so-called “black sheep” (Abrams et al., 2003). That is, with older children, members of out-groups who are not especially prototypical of the groups may be preferred over members of the in-group who are deviant from the in-group norms.

Play

Whereas preschoolers’ play involves a great deal of spontaneous and unstructured fantasy and pretense, this type of play declines steadily across middle childhood, to the point of being almost entirely absent by the end of this period (Baumeister & Senders, 1989; Rubin et al., 1983). Simple roughhousing, or rough-and-tumble play, also declines with age, although it does not disappear entirely, at least among boys (Boulton, 1996; Pellegrini, 2002; Pellegrini & Smith, 1998). Instead, the cooperative play of elementary school-age children increasingly involves adult-organized activities (e.g., playing sports) or games with formal (e.g., dodgeball, kickball, board games) or informal (e.g., tag, king-of-the-mountain, hide-and-seek) rules. A common aspect of these activities, and one which sets them apart from earlier peer activities, is that they involve increasingly greater divisions of labor, differentiation of roles and status, teamwork, and leadership (Rubin et al., 1983).

Aggression, Conflict, and Gossip

As noted, the preschool years appear to be critical years for learning to regulate aggression (Tremblay et al., 2005). Accordingly, most children who show elevated levels of physical aggression in preschool or kindergarten typically show important reductions of those behaviors as they enter the period of middle childhood and formal schooling. Children who do not display this expected decrease in aggression appear to be at increased risk for antisocial and aggressive behavior later throughout this period and even into adolescence and adulthood (e.g., NICHD Early Child Care Research Network, 2004; Tremblay et al., 2005). It is highly unusual, in fact, to identify aggressive children in middle childhood who do not have a history of aggressiveness extending backward to the preschool years (Brody et al., 2003). In addition, along with a general decline there is a change in the nature of aggression from preschool to later childhood such that verbal aggression (insults, derogation, threats) gradually replaces direct physical aggression over this period (Bierman, 2004; Underwood, 2003). Further, relative to early childhood, aggressive behavior in middle childhood is less instrumental (directed toward possessing objects or occupying specific space) and more specifically hostile toward others. Social-cognitive advances during middle childhood allow children to recognize the hostile

nature of some aggressive acts, which in turn may instigate increased retaliatory aggression (Coie & Dodge, 1998). Social-cognitive developments during middle childhood may also contribute to increased indirect or relational aggression, which involves attempts to harm others through relationship processes such as gossip and exclusion (Crick & Grotpeter, 1995; Underwood, 2003). Children who continue to exhibit high levels of verbal or physical aggression during the middle childhood years face a high risk of peer rejection (Bierman, 2004).

Gossip, especially humorous gossip, increases in salience and frequency among friends at this time (Parker & Gottman, 1989). Like those of adults, the spontaneous conversations of preadolescents ordinarily contain many references to the personal qualities, behaviors, and affairs of others (Eder & Enke, 1991; Gottman & Mettetal, 1986; Parker, Teasley, Meissner, & McClellan, 1994). In everyday usage, the term *gossip* may be mistakenly used in a restricted way to apply only to derisive comments made about outside others (Fine & Rosnow, 1977). Gossip technically encompasses all evaluative comments or conversations about third parties. Hence, admiring as well as pejorative statements made by children about others represent gossip (Fine & Rosnow, 1978; Gottman & Mettetal, 1986; Parker et al., 1994). A shared property of all gossip, however, is that the target or targets of discussion are not present, and thereby are not directly party to the conversation (Eder & Enke, 1991). This behind-the-back quality lends gossip some of its most distinctive and important interpersonal features, and distinguishes it from other significant forms of evaluative talk, such as self-disclosure or public ridicule.

As a form of speech, gossip has attracted intermittent scholarly attention over the years for its presumed roles in children’s groups, relationships, and individual development (e.g., Eder & Enke, 1991; Gottman & Mettetal, 1986; Suls, 1977). In groups, for example, gossip may increase cohesion by clarifying and enforcing behavioral norms. Further, differential access to gossip among members has been shown to correlate with group social standing and acceptance (Parker & Seal, 1996). In relationships, participating in gossip about others may bring partners’ understanding of social events and norms into closer agreement, contributing to a sense of similarity (Gottman, 1983). Observational studies suggest that children find gossip with their friends highly entertaining and use gossip as a basis for building solidarity against others through self-disclosure (Gottman, 1983; Gottman & Mettetal, 1986; Parker & Gottman, 1989; Rysman, 1977). Finally, for individuals, gossip is a form of self-expression. By gossiping about others, individuals may enhance their self-understanding through social com-

parison, and discrediting others publicly may help children project and maintain a positive self-image in areas of private concern (Fine, 1981; Fine & Rosnow, 1978; Suls, 1977).

At the beginning of middle childhood, children appear to possess a healthy skepticism of gossip, at least in the absence of clear evidence attesting to the veracity of the gossipers' claims (Kuttler, Parker, & LaGreca, 2002). With age, however, this skepticism appears to wane somewhat, even in the face of evidence that the gossip may harbor ulterior motives (Kuttler et al., 2002). Ironically, then, even as they appreciate the potential unreliability of rumors, older children express less skepticism surrounding this information than do younger children. Perhaps older children are less concerned than younger children with the accuracy of the content of gossip than with using gossip to reaffirm group membership, reveal peer group attitudes, and manipulate others' inclusion in or exclusion from the group (Eder & Enke, 1991).

Prosocial Behavior

Reliable age trends have not been observed across middle childhood in children's general disposition to behave in a cooperative, helpful, or generous way toward peers. Many researchers note that prosocial behavior toward peers generally increases with age over this period (see Fabes et al., 1999, for a review). Others, however, note that older children may actually help and share less than preschoolers (e.g., Radke-Yarrow, Zahn Waxler, & Chapman, 1983). Increased concerns with self-interest, fairness, autonomy, relationship obligations and other factors may enter into older children's decisions regarding sharing and helping (Bigelow et al., 1996). Thus, a better description of the pattern of growth and maturation in this connection is one of increasing complexity, flexibility, and responsiveness to situational, intrapersonal, and interpersonal exigencies (Bigelow et al., 1996). The development of prosocial intentions and behavior over this age span does not appear to reflect a single unfolding skill. Rather it appears to reflect a complex confluence of developmental changes.

Friendships

Middle childhood spans a period of considerable transformation in children's understanding of friendship. These changes have been charted by Selman (e.g., 1980; Selman & Schultz, 1990), among others (e.g., Berndt & Perry, 1986, 1990; Bigelow et al., 1996; Damon, 1977; Youniss, 1980). Selman's framework is perhaps the best articulated, although interested readers are encouraged to consult the notable work of Bigelow et al. as well. According to Sel-

man, prior to middle childhood, children's understanding of friendship is little more than the concept of momentary playmate. Chief among the constraints in preschoolers' thinking about friendship are difficulties they have in distinguishing their own perspectives from those of others, and in appreciating the distinction between the psychological versus manifest basis for people's behavior.

As they move into middle childhood, children's discussion of friendship and friendship issues begins to indicate a maturing appreciation that feelings and intentions, not just manifest actions, keep friends together or drive them apart. Children also begin to appreciate that others' thoughts and feelings concerning social events may differ from their own. Even in the face of this advance in perspective-taking, however, children of this age for a time remain unilaterally concerned with their own, not their partner's, subjective experiences in the relationship. This unilateral perspective subsides eventually, however, and children begin to express an understanding that both parties in a relationship must coordinate and adjust their needs and actions to one another in mutually satisfying ways. But their understanding of friendship does not include an expectation that friendships can weather specific arguments or negative events. By the close of middle childhood, however, most children understand that friendship is an affective bond with continuity over time, space, and events.

Changes in children's understanding of friendship are accompanied by changes in the patterns and nature of children's involvement in friendships across middle childhood (Denton & Zarbatany, 1996; Hartup & Stevens, 1997; Newcomb & Bagwell, 1995). The number of selections of close friends that children make has been reported to increase with age up to about 11 years of age, after which it begins to decline (see Epstein, 1986). Moreover, friendship choices are more stable and more likely to be reciprocated in middle childhood than at earlier ages, although it is not clear that either the reciprocity or stability of friendships increases across the period of middle childhood itself (Schneider, 2000). Studies in which elementary school-age children have been asked to describe their expectations in friendships also indicate that children draw sharper distinctions between the supportiveness of friends and nonfriends with age (Berndt & Perry, 1986; Bigelow et al., 1996). Moreover, children's descriptions of their friendships indicate that loyalty, self-disclosure, and trust increase with age (e.g., see Berndt & Hanna, 1995; Buhrmester & Prager, 1995; Newcomb & Bagwell, 1995 for reviews).

Many authors (e.g., Golombok & Fivush, 1994; MacCoby, 1990) have suggested that same-sex friendships

among females in middle childhood are closer than those among males and some authors are, as a result, dismissive of the importance of friendships to males (e.g., Benenson & Christakos, 2003). Developmental studies have documented numerous gender differences in children's friendships (see Golombok & Fivush, 1994; Maccoby, 1990, for reviews). Some studies suggest, for example, girls tend to self-disclose and provide greater emotional support to friends than do boys (Berndt & Perry, 1986, 1990; Buhrmester & Furman, 1987; Buhrmester & Prager, 1995; Rose & Asher, 2000; Rubin, Dwyer, et al., 2004; Zabatany, McDougall, & Hymel, 2000). Girls also report more intimacy in their friendships than do boys (e.g., Buhrmester & Prager, 1995; Parker & Asher, 1993; Prager, 1995; Rubin, Dwyer, et al., 2004) and spend more time thinking about their friends when their friends are not around (Richards et al., 1998). However, reliable differences in the longevity of boys and girls friendships have not been consistently observed (e.g., Parker & Seal, 1996) and boys and girls spend equal amounts of time with friends (Richards et al., 1998). Also, sex differences in friendship intimacy do not always emerge, sometimes are in the reverse direction, and, when significant, are not large (Berndt & Hanna, 1995). These and other lines of reasoning lead some to suggest that sex differences in friendship may be exaggerated at the expense of recognizing the many similarities in closeness, importance, loyalty, and enjoyment that exist across male and female same-sex friendships (e.g., Bigelow et al., 1996; Lansford & Parker, 1996). Further, echoing concerns of others (e.g., Gottman, 1983; Lansford & Parker, 1996; Prager, 1995), Hartup and Stevens (1997) note that closeness and intimacy in studies of friendship at this age are commonly defined in a feminizing manner (i.e., emphasis on exclusivity, self-disclosure, communal motives). This operationalization may dismiss agentic behaviors that may also underlie closeness and could provide a more balanced vision of closeness among males.

Cliques and Groups

Stable, polydyadic social groups, or cliques, also emerge in middle childhood and generally increase with age, at least through early adolescence (Cairns, Xie, & Leung, 1998; Henrich, Kuperminc, Sack, Blatt, & Leadbeater, 2000). Cliques are voluntary and friendship-based groups, and stand in contrast to the activity or work groups to which children can be assigned by circumstance or by adults. Cliques generally range in size from 3 to 10 members, and are almost always same sex (Brown & Klute, 2003). The

prevalence of cliques has generally not been investigated among children younger than 10 or 11 years of age. By 11 years of age, however, children report that most of their peer interaction takes place in the context of the clique, and nearly all children report being a member of a clique (X. Chen, Chang, & He, 2003; Kindermann, McCollom, & Gibson, 1995). Cliques appear to function, in part, as sources of definition and support for identity development during the preadolescent and adolescent years (Brown & Klute, 2003; Newman & Newman, 2001).

Vulnerabilities

We have so far highlighted the many advances in positive social interaction and relationships that mark middle childhood. But peer involvement at this age also has a less adaptive side in the appearance of more or less novel intra- and interpersonal attitudes and behaviors that are distressing, problematic, or difficult.

First, because group leaders invite some individuals and exclude others, the rise of cliques in middle childhood contributes to intergroup biases and exacerbates preadolescents' insecurity about their social position and acceptance (Adler & Adler, 1995). As a result, children of this age expend a good deal of their energy, thought, and conversation with friends buttressing their social status and guarding against rejection (Eder, 1985; Fine, 1987; Parker & Gottman, 1989). Children's desire to gain acceptance and avoid rejection is consistent with broader human motives of belonging (see Baumeister & Leary, 1995). Thus, the heightened concern with acceptance that children of this age display is understandable and may have adaptive elements. However, in certain vulnerable children, typical concern with acceptance is replaced by an excessive sensitivity to rejection (Downey, Lebolt, Rincon, & Freitas, 1998). Children with excessive sensitivity to rejection by peers readily perceive intentional rejection in minor or imagined insensitivities and disappointments and overreact in ways that compromise their group standing and social relationships. By contributing to interpersonal difficulties, sensitivity to rejection may contribute in turn to increases in internalizing and externalizing problems in these vulnerable individuals.

Second, vagaries in the reliability of social acceptance also appear to contribute to heightened self-consciousness and declines in self-esteem toward the end of this period and the start of adolescence, especially among girls (e.g., Eccles et al., 1993). In particular, perceptions of one's physical appearance grow especially central to broader self-esteem (Harter, 1999) and increasingly coupled to expecta-

tions of popularity and attractiveness to the opposite sex (Eccles, Barber, Jozefowicz, Malenchuk, & Vida, 1999). This confluence of factors, in turn, appear to increasingly compromise the self-esteem of those individuals who are not or do not feel sufficiently attractive. The self-esteem of early maturing girls during this period may also be compromised by sexual harassment by boys (Craig, Pepler, Connolly, & Henderson, 2001; Murnen & Smolak, 2000).

Third, despite a broad decline in aggression over the middle to late childhood, the risk of being bullied, appears to move in the opposite developmental direction (e.g., Espelage, Bosworth, & Simon, 2000; Espelage, Holt, & Henkel, 2003; Kochenderfer-Ladd, 2003; Kochenderfer-Ladd & Wardrop, 2001; Snyder et al., 2003). Bullying is characterized by the chronic victimization of a specifically selected target who is generally disadvantaged with respect to the balance of power (see Juvonen & Graham, 2001; Olweus, 1978, 1993). Unlike most acts of broader aggression, bullying often involves the cooperation of several more powerful individuals to victimize a less powerful one (Salmivalli, 2001). For the most part, reliable data on bullying among school-age children has only recently become available. The majority of epidemiologically oriented studies have been conducted in Europe and Australia. These studies have documented considerable variability in the prevalence of bullying, ranging from 15% to 20% in some countries to a high of 70% in others (King, Wold, Tudor-Smith, & Harel, 1996). Bullying behaviors among U.S. youth are less well understood. Recently, however, Nansel et al. (2001) conducted an analysis of data from a representative sample of 15,686 students in grades 6 through 10 in U.S. public and private schools who answered questions about bullying in the context of a World Health Organization's health behavior survey (1992). Approximately 30% of youth reported significant involvement in bullying as a bully (13%), victim (10.6%), or both (6.3%), rates in line with those reported by studies with smaller and less representative samples (see Juvonen & Graham, 2001). Bullying appeared to peak during grades 6 through 8, and declined thereafter. Bullying was more prevalent among boys than girls and the forms of bullying varied somewhat with sex. Both males and females reported that the most common form of bullying involved verbal belittling over looks or speech. Males reported being hit, slapped, or pushed more frequently than did females. Females more frequently reported being bullied through rumors and being the target of sexual comments. Taunting others about their religion or race was uncommon. Finally, consistent with other research (see Juvonen & Graham,

2001), being victimized by peers through bullying was associated with a sweeping range of psychosocial difficulties, including school difficulties, problem behavior, and loneliness.

Fourth, the rise in cliques and other nested arrangements of friendships present children in later childhood with novel interpersonal quandaries and sources of stress. Specifically, most children in middle childhood have several friends and are aware that their specific friends like or have friendships with other, outside children (Epstein & Karweit, 1983; George & Hartmann, 1996; Parker & Seal, 1996). Children's social adjustment may be facilitated by having many friends (Newcomb et al., 1999) or when one's friends are well connected socially (Sabongui et al., 1998). However, social life is also more complex in these circumstances. For example, the presence of outsiders may preempt opportunities for frank discussion between friends and coordination of social activities may be more complicated in groups larger than two (Benenson, Maiese, et al., 2002; Benenson, Nicholson, Waite, Roy, & Simpson, 2001; Lansford & Parker, 1999). In addition, outsiders will be sources of tension and conflict for friends if partners are squeezed between their loyalty to their friend and the obligations to others (Asher et al., 1996; Selman, 1980). Even when such dilemmas can be avoided, the time and emotional commitments that partners make to outside peers may still create problems for friends in the middle years. In particular, if young adolescents perceive outsiders as threatening the quality, uniqueness, or survival of their friendships, feelings of jealousy can arise and pose challenges to the partner, the perceived interloper, and the encompassing peer group (Parker, Low, Walker, & Gamm, 2005). Indeed, recent research suggests that jealousy over friends accounts for a good deal of the aggression and victimization in peer groups that occurs at this age and that individuals with low self-esteem are particularly vulnerable to this experience (Parker et al., 2005).

Finally, emerging evidence suggests that, along with enormous growth in positive peer relationships, later childhood also marks the period of growth in mutual antipathies, or so-called enemy relationships (see Hodges & Card, 2003). Very little is known about the prevalence of mutual antipathies among children and adolescents or when, precisely, these relationships emerge. Although some estimates indicate that these types of relationships are rare (e.g., Abecassis, 2003; Abecassis, Hartup, Hase-lager, Scholte, & Van Lieshout, 2002), evidence from several recent studies suggests that they may be quite commonplace, affecting from one to two out of every three

children (Parker & Gamm, 2003; Rodkin, Pearl, Farmer, & Van Acker, 2003). Enemy relations between two children tend to be short-lived relationships and children who are not well accepted generally or who have negative behavioral profiles tend to be involved more often in enemy relationships. However, enemy relationships are also quite personal. Parker and Gamm (2003), for example, examined how enemies viewed one another and compared partners' perceptions to how these children were viewed by the larger peer group. Not surprisingly, children viewed their enemies negatively. However, children seemed to have uniquely negative perceptions of their enemies, views not necessarily shared by the wider group. Although these perceptions might be due to cognitive bias, other evidence suggested that they reflected a uniquely negative interaction history between the individuals who disliked one another. Children were especially likely to view their enemies as jealous and possessive over friends, even when those individuals did not have a reputation for jealousy more widely. Finally, the importance of enemy relationships for adjustment is indicated by evidence that children who are more involved in enemy relationships experience greater loneliness and dissatisfaction, even after controlling for their adjustment with friends and broader acceptance or rejection in the peer group (Parker & Gamm, 2003).

Developments in Adolescence

Many developments in peer relationships during adolescence continue trends begun in middle childhood, others reverse earlier trends, or otherwise represent developmental discontinuities. For example, the trend in middle childhood toward spending increasingly substantial amounts of time with peers continues in adolescence. This fact is readily apparent to anyone familiar with adolescents, but the results of formal assessments can be quite startling. For example, Csikszentmihalyi and Larson (1984) had adolescents indicate their activities, moods, and companions at random intervals across a 1-week period. They calculated that during a typical week, even discounting time spent in classroom instruction, high school students spend almost a third (29%) of their waking hours with peers. This is an amount more than double the amount spent with parents and other adults (13%). Moreover, adolescent peer interaction takes place with less adult guidance and control than peer interaction in middle childhood. Adolescents feel an especially strong imperative to be out with peers on the weekend, and high school teens who are alone

on Friday or Saturday nights may be extremely lonely (Larson & Richards, 1998).

Friendship Advances

Adolescents have been reported to have fewer friends on average than children in middle childhood (Epstein, 1986). Nonetheless, same-sex friends account for an increasingly larger proportion of adolescents' perceived primary social network, and friends equal or surpass parents as sources of support and advice to adolescents in many significant domains (see Van Lieshout, Cillessen, & Haselager, 1999). In a review of developmental trends in friendship selection, Epstein (1986) concluded that the stability of adolescent friendships is generally low, but increases with age. Subsequent research by Berndt and his colleagues (Berndt, Hawkins, & Hoyle, 1986; Berndt & Hoyle, 1985), however, indicates that most adolescent friendships are stable over the school year, and any developmental trend toward increasing stability is slight. School transitions, such as at entry to middle school, junior high school, and high school can disrupt the maintenance of friendships (Berndt, 1999; Berndt, Hawkins, & Jiao, 1999; Hardy, Bukowski, & Sippola, 2002; Wargo Aikins, Bierman, & Parker, 2005). As with transitions at younger ages, youth who have the skills to form friendships prior to a major adolescent transition, such as to junior high, are more likely to be able to develop positive relationships the next year than youth whose friendship skills are less well developed. In turn, youth with high-quality friendships, marked by greater intimacy, openness, and warmth, are more likely to maintain these relationships over the transition (Wargo Aikins et al., 2005).

One hallmark of friendship in adolescence is an increased emphasis on intimacy and self-disclosure (Van Lieshout et al., 1999; Zarbatany et al., 2000). Interviews and self-report assessments with adolescents consistently indicate that adolescents report greater levels of intimacy in their friendships than do younger children (Furman & Buhrmester, 1985; Sharabany, Gershoni, & Hofman, 1981; Youniss & Smoller, 1985). Further, observations of adolescent friends indicate that intimate self-disclosure becomes a salient feature of friendship interaction at this age (Gottman & Mettetal, 1986; Parker & Gottman, 1989). Parker and Gottman (1989) speculated that salience of self-disclosure in friendship at this age is proportionate to the role it plays in assisting adolescents' efforts to understand themselves and their own and others' significant relationships. These authors noted that self-disclosure is sometimes apparent in the interactions of younger friends. However, in adolescent friendships, unlike at earlier ages,

self-disclosure prompts lengthy and sometimes emotionally laden, psychological discussions about the nature of the personal problems and possible avenues to their resolution.

Adolescence also heralds a final and key advance in the individual's abstract understanding of friendship (Selman & Schultz, 1990). Preadolescents understand a great deal about the reciprocal operations and obligations of friendship, about the potential of friendships to withstand conflict, and about the psychological motives that motivate friends' behavior. But preadolescents' understanding of issues such as trust and jealousy in friendship is very narrowly tied to their perceptions of loyalty and friendship exclusivity. In particular, preadolescents tend to view friendships in overly exclusive terms. They regard relationships with third parties as inimical to the basic nature of friendship commitment. The significant change at adolescence, however, is that individuals begin to accept the other's need to establish relationships with others and to grow through such experiences. In particular, adolescents recognize an obligation to grant friends a certain degree of autonomy and independence. Thus, their discussions of friendship and friendship issues display more concern with how the relationship helps the partners enhance their respective self-identities and jealousy over friends declines across adolescence (Parker et al., 2005).

Cliques and Crowds

As in middle childhood, cliques are readily observed in adolescence, and membership in cliques is related to adolescents' psychological well-being and ability to cope with stress (Hansell, 1981). Brown (1990) argued that structural features of the transition to high school may account for some portion of the attraction of early adolescents to cliques, and the tendency for cliques to become increasingly heterosexual with age. Brown noted that the size of high schools and the fact that students are no longer assigned to self-contained classrooms mean that children of this age must confront a large and constantly shifting array of peers, many of whom are strangers. "Securing one's place in a clique prevents a student from having to confront this sea of unfamiliar faces alone. Including members of the opposite sex in one's circle of friends ensures participation in the heterosexually oriented series of school-sponsored social activities (mixers, proms)" (p. 181).

Whether attraction to cliques declines into late adolescence is not clear, however. In sociometric analyses of the clique structure of a large school, Shrum and Cheek (1987) found a sharp decline from 11 to 18 years of age in the proportion of students who were definitely clique members,

and a corresponding increase with age in the proportion of children who had ties to many cliques or children whose primary ties were to other children who existed at the margins of one or more cliques. This pattern would appear to fit with data suggesting that both the importance of belonging to a group and the extent of intergroup antagonism decline steadily across the high school years (see McLellan & Pugh, 1999). However, not all studies are supportive of such a trend (see Cairns et al., 1998). Age related changes must also be considered in relation to context. Montemayor and Von Komen (1985) found few age-related changes across the teen years in size of in-school groups. However, out-of-school group size increased as children grew older.

Whereas cliques represent small groups of individuals linked by friendship selections, the concept of peer subcultures, or crowds (Brown, 1990; Brown & Klute, 2003), is a more encompassing organizational framework for segmenting adolescent peer social life. A *crowd* is a reputation-based collective of similarly stereotyped individuals who may or may not spend much time together (Brown, 1990; Brown & Klute, 2003). Crowds are defined by the primary attitudes or activities their members share. Thus, crowd affiliation is assigned through the consensus of peer group, not selected by the adolescents themselves. Brown (1990) lists the following as common crowd labels among high school students: jocks, brains, loners, rogues, druggies, populars, and nerds (see also Strouse, 1999). Crowds place important restrictions on children's social contacts and relationships with peers (Brown, 1989; Eder, 1985), channeling adolescents toward certain friendships and away from others (Brown & Klute, 2003). For example, cliques are generally formed within (versus across) crowds, and adolescents report that most of their close friends come from their crowd (Brown & Klute, 2003). Crowd labels may also constrain children's ability to change their lifestyle or explore new identities (Kinney, 1999). For their part, however, many adolescents identify with the crowds to which they are assigned (Pugh & Hart, 1999) and are mindful of the social stimulus value of certain crowd memberships (e.g., deviant crowds) and actively use crowd affiliations to manage their public social identity (Kinney, 1999). Also, considerable mobility is present in crowd membership across the high school years (Strouse, 1999).

Crowd membership is an especially salient feature of social life to adolescents, and children's perceptions of crowds change in important ways with age. For example, the prototypicality and exhaustiveness of crowd labels wax and wane with development. O'Brien and Bierman (1987) reported a general shift from 13 to 16 years in the basis by

which students identify and describe the crowds and other significant groups in their school. Whereas preadolescents and young adolescents focus on group members' specific behavioral proclivities, older adolescents focus on members' dispositional characteristics and values. Brown and Clasen (1986) found that, when students were asked to name the major crowds in their school, the proportion of responses that fell into typical crowd categories rose from 80% in 6th grade to 95% in 9th grade, and then fell steadily through 12th grade. The average number of crowds named increased across development, from just under 8 at 11 years to over 10 by 18 years. Adolescence also marks the appearance of crowd types (e.g., druggies, brains, punkers) that are rarely mentioned by younger children. Finally, the percentage of students who are able to correctly identify their peer-rated crowd membership increases with age (Brown & Klute, 2003).

Romantic Relationships

Romantic relationships flourish during the adolescent years, evolving from shorter-term "experiments" to longer-term alliances based on personal and relational values (Collins, 2003; Collins, Henninghausen, Schmit, & Sroufe, 1997). Reports of dating involvement among adolescents increase from 25% at age 12 to 75% at age 18 (Carver, Joyner, & Udry, 2003). The duration of romantic relationships also increases during the adolescent years, with 35% of 14- to 15-year-olds and 55% of those 16 or older reporting relationships that lasted for 11 months or more (Carver et al., 2003).

Brown (1999) outlined the progression of adolescent romantic relationships from a developmental-contextual perspective. According to Brown's model, the evolution of adolescent romantic involvement is highly sensitive to the peer context and corresponds with the course of individual identity development. During the initiation phase, concern with the quality of romantic relationships is overridden by attempts to establish a sense of efficacy as a participant in the emerging romantic culture. Adolescents realize that their romantic relationships are closely tied to their social image during the status phase, and thus their selection of romantic partners is increasingly driven by peer perception. During the affection phase, romantic relationships become more personal and less susceptible to the influence of the peer group. Adolescents in the affection phase experience heightened emotional intensity in their romantic relationships as they seek greater intimacy with their partners. Finally, pragmatic concerns about the possibility of long-term commitment supplement the emotional intensity of the affection phase during the bonding phase.

Although romantic relationships seem to appear out of the blue during the preadolescent and adolescent years, important connections between early peer experiences and adolescent romantic relationships exist (e.g., Connolly, Craig, Goldberg, & Pepler, 2004; Connolly & Goldberg, 1999; Shulman, Levy-Shiff, Kedem, & Alon, 1997). For instance, experiences of intimacy with friends and discussions about romantic involvement among friends shape adolescent romantic expectations and readiness. Peer groups also establish norms and provide guidance and support for romantic relationships, and the progression from single-sex to heterosexual peer groups during the preadolescent and adolescent years creates access to potential romantic partners. In turn, adolescent romantic relationships impact existing same-sex peer relationships and friendships. Indeed, romantic relationships promote intimate self-disclosure and elicit support among friends (Connolly & Goldberg, 1999).

Vulnerabilities

Peer experiences play an essential role in adolescents' identity development. Through their involvement in friendships and group activities, adolescents are exposed to norms and values that differ from those in their homes. Discussions with peers and friends, in particular, assist adolescents with understanding themselves and their values (Parker & Gottman, 1989). Friends in adolescence probably have no greater intrinsic influence over one another than at earlier ages (Berndt, 1999). Nonetheless, there exists concern that adolescents' involvement in peer groups contributes to a sharp and unhealthy increase in conformity and decline in autonomy. Concern has particularly been expressed that adolescents promote risk taking and other compromising behaviors in one another (e.g., Fisher & Bauman, 1988; Urberg, Cheng, & Shyu, 1991).

Evidence does support the idea that adolescents are less behaviorally autonomous of their friends than they were at younger ages and less autonomous of friends than of their parents (Fuligni, Eccles, Barber, & Clements, 2001). Further, time use data collected in a North American sample suggest that alcohol and drug use, especially on weekends, are inseparable from companionship with friends for a substantial proportion of adolescents and that partying with groups of friends on Friday and Saturday nights is a peak time for high risk behavior (Larson & Richards, 1998). Additionally, a large number of studies document similarity among members of friendship groups in behaviors such as delinquency, substance use, and early or unsafe sexual intercourse (e.g., Dishion, Capaldi, Spracklen, & Li, 1995; Keenan et al., 1995; Poulin et al., 1999). These studies have

been interpreted as evidence of peer pressure toward deviant behavior in adolescence.

Berndt (1999) cautions that similarities in deviant behavior in friendship dyads or groups partly reflect selection influences, such that individuals with deviant or aggressive tendencies tend to seek out and prefer one another. Moreover, as Berndt notes, friends have a stronger influence over one another's positive or neutral behaviors than antisocial behavior and for the most part adolescents do not anticipate that their friends will react negatively if they resist friends' invitations to engage in deviant activities. Nonetheless, convincing work by Dishion and his colleagues (Dishion et al., 1995, 1996) supports the view that social processes in friendship groups are associated with an escalation of problem behavior in vulnerable adolescents. Specifically, observations of friendship dyads indicate that relationships composed of antisocial teens respond more positively to and reinforce conversation related to rule breaking and deviant behavior than do dyads of nondeviant teens. In turn, involvement in these so-called deviancy training conversations with friends at younger ages is associated with an increase likelihood of escalating deviant behavior and rule breaking in dyad members over ensuing years (see also Keenen et al., 1995).

Apart from the brief occasions during school hours when they are involved in unstructured time with friends, adolescents generally report negative moods during weekdays at school (Csikszentmihalyi & Larson, 1984). In contrast to younger ages, time with peers on weekend evenings emerges as the emotional high point of the adolescent week. These changes in the emotional rhythms of the week are consistent with unprecedented interest and priority that adolescents ascribe to relationships with friends and romantic partners. Not all individual adolescents are able or willing to devote unprecedented time to peer activities on weekends, however, and adolescents who fall short of their own or others' expectations for social involvement may experience unprecedented and acutely negative emotions and loneliness. In their study of time use and mood during this period, for example, Larson and Richards (1998) noted that, while being alone is not generally more aversive to adolescents than to younger children, being alone on a Friday or Saturday night specifically is. Adolescents see Friday and Saturday nights as a time of the week when the most exciting peer group events happen and being alone during this time is especially painful.

Finally, although participation in dating and other forms of romantic involvement with peers of the opposite sex is a significant and welcomed developmental milestone for most heterosexual adolescents (Collins et al., 1997; Collins &

Sroufe, 1999), the emergence of this new form of relating in adolescence is neither sudden nor smooth (e.g., Davila, Steinberg, Kachadourian, Cobb, & Fincham, 2004). Instead, as noted, participation in dating and romantic relationships occurs gradually in the context of networks of same-sex friendships (Brown, 1999; Connolly & Goldberg, 1999). The addition of dating partners to an existing network of friends is fraught with social challenges, and in specific friendships, the onset of dating can create a complex social triangle of potential tension (Clark-Lempers, Lempers, & Ho, 1991; Larson & Richards, 1991). As individuals begin spending more time engaged in activities with their dating partners, their time available for activities with existing friends may diminish noticeably. As a result, existing friends, especially those who have not yet begun dating themselves, may regard themselves as neglected and feel lonely (Roth & Parker, 2001). Even where established levels of contact are maintained, existing friends may resent the perceived encroachment into previously sovereign aspects of their partner's life (e.g., serving in the role of confidant). For their part, dating individuals, notwithstanding their excitement over their romantic involvements, may perceive themselves as less similar to their friends than previously or experience guilt over their neglect of existing friends. In the extreme, dating individuals may come to see their friends' frustration and impatience with them as unfair, misdirected, and motivated by petty envy (Roth & Parker, 2001).

Comment

Progress in peer relationships is not a simple unfolding developmental sequence, but, rather, a complex braiding of developmental changes across many levels of description, including the intrapersonal (changes in social understanding and concerns), the interpersonal (changes in the frequency or forms of specific behaviors), the dyadic (changes in qualities of friendships or patterns of involvement in friendships), and the group (changes in configurations of and involvement in cliques and crowds). What is more, development must be described as interlocking across levels. For example, we discussed developmental changes in how children view their behavior, their friendships, and the salient peer groups in their schools. And friendship experiences change children's expectations of friends; but changing friendship expectations lead children to change friends or to take existing friendships in new directions.

In addition, the history of the study of social development has been one of allegiance to dispositional rather than situational explanations of developmental change (Higgins

& Parsons, 1983). In other words, it has been common to assume that the impetus for major developmental change rests in facets of individual development (cognitive growth, physical maturation, etc.) rather than in the regularities of the organizational features of the social-cultural matrix within which the individual is embedded. Our review makes the limitations of this assumption apparent. Organizational features of the environment help to define the timetable for many developments in peer relationships. Were status hierarchies not such a salient structural feature of social life in middle childhood, it is doubtful that children of this age would express as much concern over this issue, and that gossip would play as central a role in their conversations as it does (Parker & Gottman, 1989). Likewise, as Brown (1990) noted, somewhat facetiously, that for too long the tendency has been to regard adolescents' interest in and allegiance to cliques and crowds as a collective expression of a biologically timed herding instinct, rather than recognize that the depersonalized and complex routine of high school can operate to increase young teenagers' motivations for this form of involvement with peers. Without attention to the social-cultural matrix underlying development, our understanding of many of the major mileposts in the development of peer relationships would be hopelessly handicapped.

PEER INTERACTION IN DEVELOPMENT AND SOCIALIZATION

The role of peer interaction in development and socialization has been discussed in many contexts and from a diverse range of theoretical perspectives. No single framework has emerged for organizing this eclectic array of theoretical and other lines of argument, any more than a single framework exists for describing the influence of mothers, fathers, siblings, grandparents, teachers, schools, communities, and the like on development. Indeed, different authors and traditions have tended to emphasize different aspects of the process and outcome of peer interaction and relationships. However, several broad perspectives seem especially important to recognize, both for their influence on scholarship in this area and for their contrasting views of the significance of children's peer experiences.

Perspectives from Personality Theory

The study of personality, with its emphasis on how and why one individual differs from another, would seem to be a natural venue for discussion of the role of peer in social-

ization and, indeed, children's peer experiences have surfaced from time to time as an important socialization context in several grand theories of personality development.

Psychoanalytic and Neo-Psychoanalytic Views

Childhood peer experiences do not figure prominently in most psychoanalytically inspired grand theories of personality development. Sigmund Freud, Erikson, Fromm, Mahler, Horney, Adler, and Jung, for example, devoted only tangential attention to children's friendships and peer experiences. Instead, these theorists focused primarily on the contributions of parents to children's healthy self-perceptions and behavioral functioning and tended to dismiss the importance of peer relationships or downplay their significance. Whereas the individual who begins life with adequate relationships with parents is assumed to succeed in peer relationships, the peer experiences themselves are not seen as central to adaptive or maladaptive personality development (Adelson & Doehrmann, 1980; Grunebaum & Solomon, 1987; Youniss & Smoller, 1985).

An exception to this general trend is the attention devoted in the psychoanalytic framework to peer experiences at adolescence. Psychoanalytic authors have supposed that adolescents are drawn to friendships and peer groups in reaction to intrapsychic turmoil (see Blos, 1979; Douvan & Adelson, 1966; A. Freud, 1952). As articulated principally in the work of Anna Freud (1952) and Blos (1962), hormonal changes at puberty repotentiate sexual and aggressive drives to such an extent that children's earlier, hastily constructed defenses against Oedipal feelings are seriously compromised and threatened. As refuge from these reawakened drives, children seek the companionship of peers at this time (Douvan & Adelson, 1966).

Blos (1979), in particular, has suggested that changes at adolescence precipitate a second individuation process (the first, described by Mahler, 1952, occurring in very early childhood) or severing of parental identifications and internalizations. According to Blos, adolescents must shed their family dependencies and loosen their infantile object ties to parents to become members of the adult world. Within Blos's widely accepted framework, attachment to peers and identification with peer groups can play an important role in this process for several reasons:

- Because peers can serve as important sounding boards without arousing anxiety or guilt, adolescents can use discussions with peers to resolve internal conflicts.
- The peer group respects competencies, allowing the adolescent to develop an identity based on personal skills, especially athletic and social ones.

- The peer group provides practical and personal guidance in social situations, especially in heterosexual relationships and behavior.
- The peer group provides honest and critical evaluative feedback about the individual's behavior and personality attributes.

In Blos's view, because adolescents cannot find sexual gratification in the family, and in order to sever family dependencies, they turn to the peer group for support and security. Other psychoanalytic authors are less sanguine about the shift in dependency to peers at adolescence, though no less convinced of its necessity. Douvan and Adelson (1966) worried that in an attempt to free themselves from the control and restrictions of parents, adolescents may fall prey to the tyranny of a peer group, which requires conformity in return for security.

Whatever their specific merits, the claims of theorists such as Douvan, Adelson, Anna Freud, and Blos rest in an important way on assumptions about adolescents' intrapsychic turmoil and emotional lability. These assumptions have been difficult to substantiate, and, indeed, have been challenged in many instances or in specific ways (e.g., Csikszentmihalyi & Larson, 1984; Eccles et al., 1993; Offer, Ostrov, & Howard, 1981). That adolescence heralds a dramatic increase in children's interest in and attachment to peers seems undeniable, as we have discussed.

Sullivan's Psychiatry of Interpersonal Relationships

The psychiatrist Sullivan's (1953) views on children's and adolescents' peer relationships and friendships are similar in some ways, and sharply contrasting in others, to those of classic psychoanalysts, and have received a great deal of recent attention (e.g., Bigelow et al., 1999). Sullivan's formal theory of personality development is fraught with fanciful and arcane constructs, but his observations on the growth of human social motives and relationships have proved surprisingly trenchant. Like Sigmund Freud, Sullivan accepted that underlying biological drives motivate much of human behavior. In contrast to Sigmund Freud, however, Sullivan assumed that anxiety is unavoidable, always has an interpersonal context, interferes with need fulfillment, and leads individuals to construct elaborate security operations to minimize the experience. An important construct in Sullivan's theory is that of personifications, or mental representations of self and others based upon one's accumulated experiences interacting in personal relationships. Sullivan's construct of personifications is quite close to

Bowlby's (1982) better-known hypothesized internal working models, and may have influenced Bowlby's views (Bretherton, 1991).

Sullivan also described the emergence of five basic social needs across the period from infancy to adolescence: tenderness, co-participation in playful activity, acceptance by others, interpersonal intimacy, and sexual contact. According to Sullivan, these needs were fulfilled by specific individuals—parents, peers, same-sex best friends, and opposite-sex partners—in both a sequential and cumulative fashion. Of interest, the period of late childhood or the juvenile era (ages 6 to 9 years) is marked by the increase in the need for acceptance by peers and the development of compeer relationships founded along lines of egalitarian exchange. Somewhat later, during the period of preadolescence (ages 9 to 12 years), children's needs shift from a more general need for group approval to a need for a close, intimate tie to a specific other same-sex peer, or chum. *Chumships* are true intimate relationships, prototypical of later love and other collaborative relationships; chumships revolve around the expression of consensual validation of one another's viewpoints and self.

In addition to offering a general age/stage descriptive framework, Sullivan speculated on the many positive and negative interpersonal and intrapersonal consequences of peer experiences for children. For example, he considered the development of skills for cooperation and compromise, then competition and perspective-taking, empathy, and altruism to emerge from peer experiences in the juvenile and preadolescent eras, respectively. He also emphasized the role of peer experiences in constructing and correcting children's perceptions of self through consensual validation. And, along lines similar to the concept of a developmental deviation in developmental psychopathology, Sullivan offered speculations about malevolent transformations that might accompany developmental arrests of one form or another at specific periods of childhood. Children showing forms of developmental arrest included the malevolent child, the isolated child, the disparaging child, and the ostracized child.

Sullivan had a particularly deep interest in, and concern with, the affective consequences of peer experiences for children. For example, he offered many speculations as to the motivational origins of loneliness, its relation to estrangement in peer relationships, and its role in development and psychopathology. Sullivan defined loneliness as "the exceedingly unpleasant and driving experience connected with the inadequate discharge of the need for human intimacy, for interpersonal intimacy" (p. 290). He felt that intimacy and loneliness defined reciprocal sides of the

same developmental-motivational coin, the need for interpersonal integration. According to Sullivan, loneliness “so terrible that it practically baffles recall” (p. 261) ordinarily was not experienced until after preadolescence, although precursors of loneliness could be found throughout development. In preadolescence, the potential of the loneliness experience becomes “really intimidating” (p. 261). At this age, loneliness arises out of “the need for intimate exchange with a fellow being, whom we may identify as a chum, a friend, or a loved one—that is, the need for the most intimate type of exchange with respects to satisfaction and security” (p. 261). In Sullivan’s view, loneliness rather than anxiety was the motivational force behind most significant distortions of development.

Finally, Sullivan also stressed the therapeutic potential of peer experiences. He believed that the supportive atmosphere of childhood friendships could wholly or partially ameliorate certain developmental arrests resulting from earlier disturbances in relationships with parents and peers. Buhrmester and Furman (1986, p. 50) note in this connection: “It is difficult to overestimate the importance Sullivan gave to the therapeutic potential of chumships. In fact, his innovative treatment for Schizophrenia involved a form of milieu therapy in which the aim was to recreate preadolescent chumships.”

Research generally supports Sullivan’s claim that intimacy becomes salient during preadolescence, primarily within the context of same-sex friendships and his prediction regarding the role of close friendships in loneliness, the development of social perspective-taking skills, and prosocial orientations (e.g., see Hartup & Stevens, 1997). Children’s perceptions of their competence with peers also become more central to their self-definition and self-esteem in preadolescence (Harter, 1999) as Sullivan predicted. Sullivan’s provocative thesis about the therapeutic potential of friendships seems to have received less attention than other aspects of his theory, unfortunately. Nevertheless, the work of Selman and his colleagues (e.g., Selman & Schultz, 1990), though only partly motivated by Sullivan’s views, is worth citing in this connection. In Selman’s pair therapy, two young adolescents with socioemotional and interpersonal difficulties are paired, along with a therapist, for long-term therapy. The dyad is encouraged to play together and the partners are asked to reflect on their interaction together and their relationship. The aim is to achieve a restructuring of the children’s immature interpersonal functioning and understanding, improving their individual and joint capacities for engaging in productive interaction with each other and other children. Thus, a legacy of Sulli-

van’s theory can be identified in recent, productive clinical interventions.

Havighurst’s Developmental Task Approach

Havighurst (1953) drew early attention to the significance of adjustment with peers for children’s well-being and personality development. He argued that adaptation to peers can be viewed as one of many important “tasks” in development. According to Havighurst (1953, p. 2), developmental tasks are “those things a person is to learn if he is to be judged and to judge himself to be a reasonably happy and successful person.” They are tasks in the sense that “successful achievement . . . leads to [an individual’s] happiness and success with later tasks, while failure leads to unhappiness in the individual, disapproval by the society, and difficulty with later tasks” (p. 2). They are developmental in the sense that each has a period of ascendancy and is subject to arrest. Each “arises at or about a certain period in the life of the individual” (p. 2) and “if the task is not achieved at the proper time it will not be achieved well, and failure in this task will cause partial or complete failure in the achievement of other tasks yet to come” (p. 3).

According to Havighurst (1953), developmental tasks have multiple origins. Some tasks, such as learning to walk, arise mainly from physical maturation. Tasks arising from physical maturation are more universal than other tasks. Other tasks, such as learning to read, arise primarily from cultural pressure. Such tasks are culturally or subculturally relative. The expectations, values, and aspirations of the individual represent the third source of developmental tasks. Like cultural tasks, these vary with the historical cultural context of the individual.

Havighurst (1953) placed considerable emphasis on peer relationships as a task of childhood. Getting along with peers, Havighurst felt, was important in its own right, as well as for its role in helping children attain other tasks in middle childhood, including (1) the development of social skills, a rational conscience, and a scale of values; (2) the learning of appropriate social attitudes; and (3) the achievement of personal independence. He suggested that getting along with peers was a primary task in middle childhood; but he recognized that this challenge was, in a very real sense, a lifelong one. Indeed, he anticipated considerable continuity in adaptation over development, speculating: “The nine or ten year old already shows what he will be like, socially, at fifty” (p. 31). In this way, Havighurst anticipated the contemporary interest in the long-term adjustment of children with peer relationships difficulties (see Rubin, Bukowski, & Parker, 1998 for a review).

Ultimately, Havighurst's concept of developmental tasks had limited influence on human development research. However, this concept is represented in most of its essential elements, including its focus on the significance of peer relationships, in contemporary organizational or adaptational accounts of development (Sroufe, 1995). Organizational theorists, however, disagree with Havighurst's characterization of development as a series of unfolding tasks that need to be accomplished and then decrease in importance. Instead, organizational theorists stress that most developmental tasks, upon emergence, remain critical to the child's continual adaptation.

Developmental Constructivist Approaches

Besides contributing to a view of children as actively engaged in efforts to interpret, organize, and use information from the environment, developmental constructivists such as Piaget (1932) and Vygotsky (1978) have stressed how structural features of interpersonal relationships influence the development of knowledge, language, social problem-solving skills, and moral behavior. An important distinction in this framework involves the differential affordances of adult-child and child-child interpersonal exchanges, a distinction that Hartup (1989, p. 120) characterized as the distinction between horizontal versus vertical relationships:

[Children's vertical attachments are] attachments to individuals who have greater knowledge and social power than they do. These relationships, most commonly involving children and adults, encompass a wide variety of interactions among which complementary exchanges are especially salient. For example, adult actions toward children consist mainly of nurturance and controlling behaviors, whereas children's actions toward adults consist mainly of submission and appeals for succorance (Youniss, 1980). [Children's horizontal attachments are] relationships with individuals who have the same amount of social power as themselves. Ordinarily, these relationships involve other children and are marked by reciprocity and egalitarian expectations.

The concept of the differential socialization opportunities in horizontal (peer) versus vertical (adult) interpersonal contexts has been especially influential in the domains of cognitive and moral development.

Cognitive Development

Constructivist approaches to cognitive development have been reviewed in a number of connections recently (e.g., Azmitia, Lippman, & Ittel, 1999; Hogan & Tudge, 1999; Rogoff, 1997). These reviews generally conclude

that under specific circumstances, including many that occur frequently and spontaneously in the course of peer interaction, conversation with other children can promote children's perspective-taking skills, problem solving, language skills, academic achievement, scientific and logical reasoning, and a host of other important cognitive and social-cognitive accomplishments.

Piaget's (1932) influential proposal was that peers promote the advancement of one another's cognitive development through attempts to resolve discrepancies deriving from the differences in their perspectives on a problem. As children interact with other children, they become aware of the contradictions between their own view of a problem and that of their partner. This conflict provokes disequilibrium that can propel children to newer and higher levels of reasoning. Importantly, in Piaget's view it was not so much the simple exposure to the new or better problem-solving strategies of the partner, as the opportunity to confront one's own thinking that was critical; unless children appreciated the inefficiency of their old cognitive strategies they were unlikely to abandon them. According to Piaget, this type of real conceptual advance was not likely to happen in discussion with adults or others with greater status, because children were likely to unilaterally accept the conclusions of higher status individuals.

Whereas Piaget emphasized the contribution of symmetric relationships (i.e., friends, children of similar social and cognitive status), Vygotsky (1978) emphasized the contribution of asymmetric (i.e., parent-child, sibling-child, expert child-novice child) relationships to cognitive development. Thus, Vygotsky also saw peers as important to cognitive development, though by comparison to Piaget, less uniquely so.

The ideas of Piaget and Vygotsky have been explored in a great many experimental and other studies (see Gauvain, 2001). A review of this work suggests:

- In line with both Piaget's and Vygotsky's assertions, children working together can solve problems that neither child is capable of solving alone. Further, children working with other children show real cognitive advances from pre- to posttesting and these advances are stable and in most circumstances generalize to other problems.
- It is important that the partners bring conflicting perspectives to the problem; when two children share an understanding of the problem, little cognitive advance is noted.
- In line especially with Vygotsky's thinking, children also make cognitive gains when they work with partners who have a superior understanding of a problem (though this is not a prerequisite for advancement).

- Children with less advanced partners sometimes show a regression in their thinking about a task. Thus, peer collaboration is not always uniformly facilitative or even neutral. An important interactional constraint seems to be children's certainty of the correctness of their own thinking. When children are more certain of the correctness of their thinking, or the task permits children to be more certain, they are more likely to influence their partners.
- Certain types of conflicts are more likely to promote growth than others. Especially critical are "transactive" discussions—discussions that involve noticing and resolving contradictions in one's partner's logic rather than one's own logic.
- Collaborations with friends may foster greater developmental change than collaborations with nonfriends, at least when the task is a complex one requiring metacommunication skills. Friends seem more inclined to take the important steps of anticipating their partner's confusions and spontaneously justifying and elaborating their own thinking and rationales.

Overall, it appears that the research literature generally supports many of the theoretical assertions of Piaget and Vygotsky regarding the importance of peers in children's cognitive development, even as it suggests some qualifications.

Moral Development

Disputes over objects, distributions of resources, personal norms, customs and rules, respecting others, loyalty, and personal rights are all common features of peer interaction. So, too, are acts of cooperation, forgiveness, kindness, concern, respect, and altruism. In view of the ubiquity of such events, it should not be terribly surprising that peer relationships are an important context for moral development and socialization.

Psychoanalytic and social learning socialization theories have traditionally viewed moral development as children's internalization of adults' skills, knowledge, and conventions. Peer experiences generally have not figured prominently in these formulations, although social learning theorists have recognized the importance of peers as social models and reinforcers of prosocial and antisocial behavior.

Developmental constructivists such as Piaget (1932) and Kohlberg (1969) present a contrasting view. On this view, peer interaction is uniquely suited to the promotion of higher moral reasoning (and presumably behavior). Indeed, Piaget was dismissive of the ability of parents to affect any

real, meaningful change in children's development in this area. In *The Moral Judgment of the Child*, Piaget (1932) suggested that parent-child relationships were a poor context for moral development because they are marked by unilateral authority or constraint. Although children obey their parents, they do so unreflectively. As a result, the moral issues behind rules parents establish are shrouded from and necessarily mysterious to children. With peers, on the other hand, the child is aware that both participants have equal knowledge and authority. When a conflict of interest arises, the child is led to recognize that others have perspectives that differ from his or her own. Because neither of these perspectives have special authority, both children's views have an equal claim to validity, and children are motivated to use discussion, debate, negotiation, and compromise to integrate their conflicting views. The morality of peer interaction is a morality of reciprocity and mutual respect.

As might be imagined, Piaget's hypotheses about the special significance of peer interaction in moral socialization are difficult to evaluate; disentangling the contribution of peer experiences from others' influences on moral judgment is an exceedingly challenging task. However, a number of studies, reviewed by Schlaefli, Rest, and Thoma (1985) and Walker (1986), indicate that peer debate can, in fact, encourage higher levels of moral reasoning in children. In one of the best known of these studies, Damon and Killen (1982) videotaped 5- to 9-year old children in triads during discussion of a distributive justice problem. Pre- and posttests established that the children who participated in these discussions were more likely to advance in their moral reasoning than were children who discussed a similar justice problem with an adult or children who were merely exposed to the pre- and posttests. Similarly, Arbutnot (1975) found that dyads who debated moral dilemmas toward consensus showed more change in moral reasoning than dyads who passively heard arguments about the dilemmas or who performed extraneous tasks.

These studies and others further suggest, in line with Piaget's thinking, that a crucial impetus to developmental change in the context of peer discussion is the process of transactive discussion. Transactive exchanges are exchanges in which each discussant performs mental operations on the reasoning of his or her partner (e.g., critiques, refinements, extensions, paraphrases of the partner's ideas). Children have been found to employ more transactive statements in the discussions of moral issues with peers than their discussions with mothers (Kruger & Tomasello, 1986), and the use of transactive statements has been found to be an important

condition for moral developmental change through peer interaction (e.g., Damon & Killen, 1982).

Cognitive-Social Learning Perspectives

Writers influenced by cognitive-social learning theory have emphasized the ways in which peers extend, elaborate, and alter children's social skills, behavioral tendencies, and self-attributions. According to social learning theory, children generate internal rules linking social behaviors to consequences (praise, criticism, rebuke, rejection) and guide their behavior according to these rules. In part, these rules are learned through direct experience of peer punishment and reinforcement; very simply, children tend to repeat behaviors their peers approve of, and they learn to inhibit actions that peers discourage. In addition, much learning is presumably also vicarious; that is, children learn through observation of other children's behavior and the consequences that other children receive for performing various behaviors. Observation of peers introduces children to new modes of behavior and to the situational and other exigencies governing their performance.

Increasingly, social learning theorists have also stressed that much behavior is controlled by self-generated consequences, concerns, and expectations as well as external forces. Children set standards of achievement for themselves, and self-administer reinforcement when those standards are met and punishment when they are not. The intensity of children's self-reinforcement or self-punishment is governed by many features, but one important factor is social comparison to peers, or the child's assessment of how well his or her behavior compares to that of other children. Bandura (1989) proposed that when children wish to estimate their competence at an activity they tend to compare their performance to that of their peers, especially children who are similar or slightly higher in ability than themselves.

Social learning theory has also emphasized the role of social comparison, and hence peers, in the development of attitudes of personal agency or self-efficacy (Bandura, 1989). Children's beliefs about their abilities, characteristics, and vulnerabilities guide their behavior by determining what actions they attempt and how much effort and persistence they invest in these.

Within the social learning framework, peers influence the developing child according to the same laws of social learning that apply to other socialization agents, including parents, teachers, and television. However, owing to the special features and challenges of membership in peer

groups, the content of what children learn from their peers is assumed to be very different in many instances from what they learn from adults. For instance, many authors note that peer experiences have powerful emotional concomitants, suggesting that children develop important emotion regulation competencies in this context (Calkins, Gill, Johnson, & Smith, 1999; Eisenberg, 2002; Eisenberg et al., 2001; Saarni, 1998, 1999; von Salisch, 2000). Observations of preschoolers, for example, suggest that friendship interaction has the implicit goal of maximizing the level of children's enjoyment during play (Parker & Gottman, 1989). For this to occur, friends must be successful in coordinating their behavior; this, in turn, necessitates that children learn skills for inhibiting action and maintaining organized behavior and attention in the face of arousal, excitement, and frustration. Other authors (e.g., Fine, 1981; Hartup, 1983) have noted the especially strong influence of peers on the amount of specific information about sex learned in early adolescence.

Particular progress has been made in the application of cognitive-social learning concepts to the study of the development of aggressive (see for example McCord, 1995; Moffitt, 1993; Nagin & Tremblay, 1999; Poulin & Boivin, 2000; Schwartz, Dodge, Pettit, & Bates, 2000; Tremblay, Mâsse, Vitaro, & Dobkin, 1995; Vernberg, Jacobs, & Hershberger, 1999; Vitaro, Brendgen, & Tremblay, 2000) and prosocial (Masters & Furman, 1981; Ollendick & Schmidt, 1987) tendencies, and to the development of sex-typed behavior (Huston & Alvarez, 1990; Moller, Hymel, & Rubin, 1992). In the last instance, for example, a great deal of research suggests preschool children reward sex-appropriate and punish sex-inappropriate behavior and toy choices (e.g., Eisenberg, Tryon, & Cameron, 1984; Moller et al., 1992). In addition to such direct influences, many authors have noted that the *de facto* gender segregation of children's play groups during most of childhood and adolescence suggests that boys and girls inhabit almost entirely separate worlds in childhood, with important implications for their social learning (e.g., Zaratany, Hartmann, & Rankin, 1990). Indeed, it has been suggested that one consequence of growing up in separate worlds is that as children learn a style of interaction that works well with same-sex peers, they become progressively less effective with opposite-sex peers (Leaper, 1994; Maccoby, 1990).

Finally, social learning perspectives have played an important role in understanding how marital distress and conflict in the home may be linked to poor social outcomes in children, including friendship difficulties and

child behaviors related to peer rejection (e.g., Du Rocher Schudlich, Shamir, & Cummings, 2004, for reviews). From a cognitive-social learning perspective, marital distress and conflict is thought to exert its negative impact on children's social adjustment indirectly, through the spillover of negative affect and behavior from the marital dyad to the parent-child dyad (Erel & Burman, 1995). Marital conflict and dissatisfaction predict negative attitudes about child rearing as well as insensitive, inconsistent, and harsh treatment of children (Wilson & Gottman, 2002). If children model these behaviors with peers, they are likely to experience rejection. Additionally spousal conflict and hostility can affect children directly by contributing to self-blame and expectations of threat (Grych & Fincham, 1990) and emotional insecurity (Davies, Harold, Goeke-Morey, & Cummings, 2002), and by providing them with models of coercive interpersonal behavior (Webster-Stratton & Hammond, 1999). Indeed, destructive and aggressive marital conflict has been linked with immediate child emotional distress and aggressive behavior; furthermore, children's negative emotional reactivity and aggressive behavior in the home and lab have been linked to internalizing and externalizing problems (Cummings, Goeke-Morey, & Papp, 2003, 2004).

Social Psychology

Because much of the core of the discipline of social psychology is dedicated to understanding the behaviors and attitudes of individuals in their groups and relationships, it might be supposed that the study of children's peer group and friendship experiences represents a rich and long-standing interface between that discipline and the discipline of developmental psychology. In fact, less deliberate cross-fertilization has occurred between these disciplines than might be supposed and appropriate (Durkin, 1995). There are signs that this is changing. For example, there have been several attempts recently to explore the developmental roots of relationship phenomena that are better understood by social psychologists focusing on adult relationships. Examples include research on children's forgiveness (e.g., Enright, Gassin, & Wu, 1992; Enright & the Human Development Study Group, 1991), sensitivity to rejection (Downey & Feldman, 1996), understanding of exclusion and black-sheep individuals who deviate from group norms (Abrams et al., 2003; Killen, Lee-Jim, et al., 2002), and jealousy (Parker et al., 2005). However, the primary exception remains the study of the features and processes of social support in childhood and adolescent friendships.

Interest in social support and its relation to mental health, physical health, and responses to stress has a long-and-storied history in social psychology. Indeed, a large body of empirical work in this tradition indicates that receiving social support, or feeling confident that support will be available when one needs it, helps adults cope more effectively with stressful events and appears to have short-term and long-term benefits for health and psychological well-being (see Cunningham & Barbee, 2000; Pierce, Lakey, Sarason, & Sarason, 1997). Adults commonly name their spouses as the person most likely to provide support during times of need (e.g., Dakof & Taylor, 1990). However, most adults also include friends as a primary source of support (Fehr, 2000). Interestingly, an individual's subjective belief that support is available is generally a better predictor of major outcomes, such as mental and physical health, than are assessments of objective support, such as indices of the size of a person's interpersonal network (see Cunningham & Barbee, 2000). Some investigators have also argued that adults' general perceptions of the availability of social support provide better buffering effects against risk than do the actual specific supportive behaviors provided by partners. The objective aspects of social support networks are affected by social skills that contribute to the development and maintenance of a broad, dense, and reliable network. However, the perception of and satisfaction with social support appears to be influenced by individuals' personality factors, such as attachment style, emotional stability, and extraversion (Von Dras & Siegler, 1997).

Drawing upon this literature, several authors have offered taxonomies of the supportive dimensions of childhood friendships (e.g., Asher et al., 1996). Although these formulations differ in specific ways, there appears to be a broad consensus concerning the dimensions that make up friendship support and the overall significance of these dimensions to children's adjustment and development (see Furman, 1996; Rose & Asher, 2000). In all, at least five major features of friendships and categories of social support have been discussed with some regularity.

A first important supportive feature of children's friendships is self-esteem enhancement and self-evaluation; that is, friendships help children develop and maintain an image of themselves as competent, attractive, and worthwhile. Because friends compliment one another, express care and concern over one another's problems, and boast to others about one another's accomplishments, friendships are thought to play an especially important role in children's self-esteem and self-image. The self-

esteem enhancing and self-validating properties of friendships have been hypothesized to be especially important when children are going through normative changes such as school transitions or puberty or undergoing stress (Sandler, Miller, Short, & Wolchik, 1989), but they are undoubtedly important at other times as well. Moreover, friendships may represent significant contexts for social comparison and hence personal understanding (Berndt, 1999).

A second important function of friendship is the provision of emotional security in novel or threatening situations. Even the simple presence of a friend may boost children's reassurance and confidence. This can have important implications for whether children are willing to explore new environments, try new behaviors, or take the kind of small and large risks often associated with growth.

Third, friendships are important nonfamilial contexts for intimacy and affection. The expression of caring, concern, and affection for one's partner have been rightly identified as important, perhaps even defining, characteristics of children's friendships. As they get older, children increasingly emphasize intimacy, self-disclosure, openness, and affection as components of friendship, both in their general beliefs about friendships and in their descriptions of their actual friendships (see Newcomb, Bukowski, & Bagwell, 1999).

Fourth, friends provide informational or instrumental assistance to one another. Like adults, children count on their friends' physical assistance with difficult or time-consuming tasks and look to their friends to provide constructive criticism, counsel, and information.

Finally, friends provide one another with companionship and stimulation. As Asher et al. (1996) note, the companionship aspects of childhood friendship provide some of the most enduring and romantic images of childhood friendship. Friends of all ages emphasize the enjoyment they derive from one another and from the activities they undertake jointly, although the nature of friendship companionship changes developmentally, of course. Successful and stimulating shared experiences contribute to a sense of shared history, joint fate, and a perception of investment in the relationship.

To date, the number of studies of children focusing on friendship support, stress, and adjustment is limited. The question of whether friendship support in childhood can offer the same strong-stress buffering role that is so celebrated in adulthood has not therefore been fully answered. The available evidence, however, supports the conclusion that friendship support among children functions similarly to that

among adults insofar as it contributes to children's ability to cope with life stressors of many types (see Belle, 1989; Compas, 1987; Dubow, Tisak, Causey, Hryshko, & Ried, 1991; Kramer & Gottman, 1992; Wentzel, McNamara-Barry, & Caldwell, 2004). How and under what circumstances supportive friendships are beneficial in helping children and adolescents weather stress is less clear. In an insightful analysis of this problem, Berndt (1989) offers the following hypotheses and conclusions, however:

- Friendships do not buffer children from stress if the friendships themselves do not survive the stressor. In other words, evidence for an inoculating effect of positive friendships is weak. Children with better friendships do not endure stressful events better than children with less adequate friendships if the stressful event separates children from their friends. School transitions and family relocations are good examples of stressful events that increase the mortality of friendships (e.g., Wargo Aikins et al., 2005). Further, the loss of important friendships under these circumstances is, in all likelihood, itself a stressful event for children.
- Supportive friendships have the greatest influence on children's adjustment when they offer the specific type of support needed to deal with a particular stressor. For example, "when a child needs help with homework, a friend who answers questions about the assignment . . . may render more effective support than a friend who simply tries to make the child feel better about his or her abilities" (Berndt, 1989, p. 318). Indeed, support that does not match the stressor may under some circumstances be less productive than no support at all.
- Finally, the child must access or take advantage of the support that is available to him or her under the stressful circumstances. In many instances, this must be an active, purposeful process. As Asher et al. (1996) note, to do so effectively, children must recognize that a problem exists, and understand the seriousness of the problem, the problem details, and the specific emotions associated with the problem. And they must ensure that their affection and advice is perceived and received as selflessly motivated and genuine.

Likewise, recent research by Rose (2002) also sounds a cautionary note. She argues that while opportunities for self-disclosure and interpersonal support within friendships have generally positive benefits for members, in some instances these discussions dominate friends' conversation and interaction together, a process labeled *co-rumination*.

Co-ruminating friends endlessly discuss and revisit problems, speculate on solutions and hypothetical outcomes, and focus on negative feelings. Rose's (2002) data indicate that, while friends, especially boys, who co-ruminate may become closer, they may also place themselves at risk for internalizing difficulties including depression.

Cooley, Mead, and the Symbolic Interaction View

The idea that children's experiences with peers contribute to the development of their self-concepts seems an especially attractive one. This proposal is at the heart of symbolic interaction theories, and, as Bukowski and Hoza (1989) noted, can in fact, be traced back to the earliest days of American psychology. One of the first authors to emphasize this point was Cooley (1902), whose ideas were later extended by Mead (1934; see Corsaro, 1985). Mead, like Cooley before him, suggested that children experience themselves indirectly through the responses of other members of their significant peer groups. Mead suggested that the ability to reflect on the self developed gradually over the early years of life, first through imitation of peers (and adults) and later primarily as a function of peer play and games. Mead argued that participation in rule-governed games and activities with peers led children to understand and coordinate the perspectives of others in relation to the self. Thus, perspective-taking experiences resulted in an understanding of the generalized other or the organized perspective of the social group. This development, in turn, led to the emergence of an organized sense of self. Therefore, to Mead, peer interaction was essential for the development, not only of perspective-taking skills, but also for the development of self-system.

Authors influenced by this perspective have emphasized the contributions of peer relationships to specific social skills and, particularly, to children's self-presentational or impression management skills for positioning oneself effectively and adaptively in social situations (e.g., Denzin, 1977; Fine, 1981, 1987). Fine (1981), for example, has argued that childhood peer relationships, especially friendships, are important arenas for testing the bounds of acceptable behavior and developing poise under stress. He noted that within the bounds of friendship, inadequate displays will typically be ignored or corrected without loss of face. In this connection, Grunebaum and Solomon (1987) observed that:

Much childhood play takes the form of deliberately perpetuating a loss of poise. Children everywhere play pranks, induce dizziness, trip one another, disarrange clothing, kid or

tease one another. In peer relations these tests of social poise help prepare the child for the maintenance of identity and self control later in life. (p. 480)

Interpretive Approaches to Peer Culture and Child Socialization

Interpretive writers have been highly critical of psychoanalytic, social learning, and other conceptualizations of socialization that describe socialization as the private and unilateral internalization of adult skills and knowledge (see Corsaro & Miller, 1992; Corsaro & Rizzo, 1988; Rizzo, 1989). In common with symbolic interaction and developmental constructivist authors, they stress children's proclivity to interpret, organize, and exploit information from the environment and thereby shape their own socialization experiences and outcomes. However, the interpretive approach extends the constructivist one by stressing that the "environment" itself is a social construction—a world of habitual interactive routines and shared understandings that permit children to participate further in social activity. In development, "children enter into a social system and, by interacting and negotiating with others, establish understandings that become fundamental social knowledge on which they continually build" (Corsaro & Rizzo, 1988, p. 880).

Interaction with peers plays an indispensable role in this process: By interacting with playmates in organized play groups and schools, children produce the first in a series of peer cultures in which childhood knowledge and practices are gradually transformed into the knowledge and skills necessary to participate in the adult world (Corsaro & Rizzo, 1988).

An especially valuable aspect of the interpretive approach to children's peer interaction is the stress placed on documenting the socially shared and culturally relevant meaning behind many of the recurrent and predictable interaction routines that make up much of the day-to-day social life of children with their peers. Corsaro (1985), for example, has described the shared concerns underlying the common spontaneous themes in preschooler's social fantasy play. More generally, interpretive authors have emphasized how children are frequently exposed to social knowledge in adult-child interaction they do not fully grasp. Such ambiguities will often go unresolved in that context because the orderly nature of adult-child interaction does not demand their resolution. However, these uncertainties may be readdressed later in the interaction routines that make up peer culture. Contrariwise, children also seem to appropriate certain elements of the adult culture to deal with practical problems in the peer culture. In such reciprocal fashion, children pro-

duce and reproduce their culture through their socialization experiences in the peer group.

Ethological and Evolutionary Insights

The application of ethological and evolutionary principles and methods to understanding children's peer experiences has waxed and waned over the decades. Excellent early historical examples include work by Blurton-Jones (1972b), Konner (1975), Rosenblum, Coe, and Bromley (1975), Savin-Williams (1979), and Suomi and Harlow (1975), among others. Ethologists Robert Cairns (1979) and Robert Hinde (1979), in particular, deserve singular credit for their efforts to bring broader attention to insights from evolution, social ethology, and developmental psychobiology to the hearth of the growing science of children's peer experiences. Work in this tradition declined over the ensuing decades, although evidence exists that this trend is reversing (e.g., Hawley, 2002, 2003). Complete treatment of the insights into peer experiences left by these perspectives are beyond the scope of this chapter and have been summarized by others to some degree (e.g., Rubin, Hastings, et al., 1998). A few footprints of this perspective bear mentioning however.

Animal Studies of Peer Deprivation

Because experiments involving social deprivation are possible with nonhuman primates, comparative social ethology has provided compelling, albeit isolated, illustrations of the necessity of experiences with age-mates for adequate adjustment. A series of classic studies by Harlow, Suomi, and associates (see Suomi, 1979; Suomi & Harlow, 1975), for example, established that rhesus monkeys reared with adequate adult but impoverished peer contact displayed inappropriate social, sexual, and aggressive behavior. Moreover, the longer such monkeys were denied the opportunity to interact with peers, the more glaring their social inadequacies. For obvious reasons there are no parallel studies with humans, but a study by Hollos and Cowan (1973) of children with extensive contact with their parents but grow up virtually without age-mates on isolated farms in Norway suggested that, compared to controls, social role-taking skills are impaired but tasks involving nonsocial logical cognitive operations are not. In other words, the problems that the peer isolated children displayed were specifically social.

Descriptive Studies of Child Behavior

A commitment to providing a detailed descriptive account of the behavioral repertoire of a species is a common

focus to all ethological work (Blurton-Jones, 1972b; Cairns, 1979; Strayer & Strayer, 1976). Over the years, then, ethologically inspired work has provided almost an encyclopedia wealth of data on children's behavior with age-mates. Much of this work was largely atheoretical. Early, classic examples include studies of sociability and social participation (Parten, 1932; Thomas, Loomis, & Arrington, 1933), assertiveness (Dawe, 1934), sympathetic and altruistic behaviors (Murphy, 1937), and aggression (Goodenough, 1931). Representative of this tradition is early work by Blurton-Jones (1972a). Blurton-Jones (1972a) observed the 25 oldest and youngest members of preschool group for over 2 hours each in 5 minute blocks using a rich taxonomy of codes built up over time and from experience. The detail apparent in Blurton-Jones's (1972a) codes are instructive. His codes included: get red face, cry, pucker, take, fixate, low frown, take-tug-grab, hit, jump, run, slap laugh, smile, watch, give, to name only a few. Factor analyses reveal at least three broad classes of purposeful behavior with peers; play versus work, aggression, and general social behavior. More detailed analysis of the associations among these behaviors produced further interesting observations. For example, toy use played an important role in precipitating aggression in the youngest children and therefore children who were not strongly attracted to toys were involved in fewer conflicts with their peers than other children.

Most contemporary efforts, however, have drawn more directly upon a priori theoretical premises based in ethological or evolutionary principles. An example is recent interest in rough-and-tumble play, or play fighting (e.g., Boulton, 1996; Pellegrini, 2003). Although rough-and-tumble play is a form of aggression, its playful tenor signals that the aggressive intent of the behavior should be discounted. Work by Pellegrini (2003), however, suggests a more complicated picture. Pellegrini reasoned that play fighting among males helps establish and preserve the broader social order, whereas male-female play fighting represents early sexual interest and courtship rituals. Consistent with this hypothesis, male-male play fighting preceded male-female play fighting during the transition to 6th grade. Moreover, careful observation of boys' rough-and-tumble play indicated that boys' and girls' understanding of this behavior depends on their experience with it. Whereas, while boys with less experience with play fighting tend to discount its hostile intent, boys with more experience better appreciate that the surface structure of play fighting can mask underlying subtle efforts at dominance and intimidation. Girls with greater direct experience with rough-and-tumble play, however, were more likely to see it

as playful than their counterparts with no experience with this form of behavior.

Ethological Insights into Social Organization

The application of ethological principles to understanding social organization has a long history and continues to yield productive findings. As an example, building on early ethological work on social dominance, Hawley (e.g., Hawley, 1999) reinterpreted and reintroduced the concept of social dominance and made a case for its relevance for the development of personality and social functioning. Her evolutionary approach led her to focus first on the *function* of behavior (competition) over the *structure* of behavior. Consequently, she views structurally distinct behaviors (e.g., prosociality and coercion) to be functionally similar (i.e., resource control strategies); resources can be won via cooperation and forging friendly alliances or aggression. This perspective challenges us to view prosociality and antisociality to be two sides of the same coin rather than opposite ends of a single dimension.

In her studies, Hawley and colleagues have demonstrated the social and adjustment implications of resource control attempts and strategy employment. Relative social dominance ranking, for example, impacts play patterns and, thus, who attends to, defers to, or imitates who as early as the toddler years (Hawley & Little, 1999). Dominant children thus not only profit from material rewards but also their competitive competence wins social prestige not enjoyed by subordinate children. According to Hawley, the social esteem of superior competitors is not a quirk of early childhood, but is maintained over the life span. Her work with adolescents has shown that the most effective resource controllers continue to be admired (and liked) by the peer group, even though they are highly aggressive. These so-called bistrategic individuals employ both prosocial and coercive strategies in ways that (1) make them extremely effective at goal attainment, (2) earn them a reputation for aggression (both overt and relational), and (3) reveal they are at the same time highly socially skilled (Hawley, 2003; Hawley, Little, & Pasupathi, 2002). In contrast to these aggressive powerholders, noncontrollers (those who make no resource control attempts) appear to be the most at risk. Even though they are very low on aggression, they are rejected and victimized by their peers, and experience the highest levels of ill-being (Hawley et al., 2002).

Insights from Attachment Theory

As Furman (1999, p. 135) has noted, "Human beings are predisposed to affiliate with known others. We are social

animals, and have been throughout the course of evolution. Natural groups are characteristic of all humans (Foley, 1987)." Bowlby's attachment theory was formulated to account for human infants' attraction to and dependence on others and to specify how early experiences with significant others, particularly adult caregivers, are carried forward in development (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1982; Bretherton, 1990; Sroufe, 1983). As expressed by Sroufe and Fleeson (1986, p. 52), one of the basic premises of attachment theory is that "The young child seeks and explores new relationships within the framework of expectations for self and others that emerges from the primary relationship." In most instances, infants' most significant earliest relationship is that with their mothers. Thus, according to the theory, the early mother-child relationship lays the groundwork for the children's understanding of and participation in subsequent familial and extra-familial relationships. Because the quality of infants' attachments with their mothers varies, children's later social outlook and success with peers is expected to vary as well.

In the case of children with secure attachment histories, an internalized or working model of relationships is built up; that is, comprised of the belief that the parent is available and responsive to one's need for protection, nurturance, and physical care. In a reciprocal fashion, the child with a secure attachment history is also expected to come to regard him- or herself as competent and worthy of parental love and nurturance. In particular, attachment theory predicts at least three specific, salutary influences on children's internal working models and ultimate success with peers. First, a secure attachment relationship with the primary caregiver promotes positive social expectations. Children are disposed to engage other children, and expect peer interaction to be rewarding. Second, their experience with a responsive and empathic caregiver builds the rudiments of a social understanding of reciprocity. Finally, through a history of responsive care and support for autonomy within the relationship, the child develops a sense of self-worth and efficacy. This internal outlook is thought to be important to promoting curiosity, enthusiasm, and positive affect, characteristics that other children find attractive.

Alternatively, when parental insensitivity contributes to the development of an insecure primary attachment, children are thought to develop an internal working model of relationships that stress their unpredictable nature, and images of themselves as unworthy and ineffectual. According to Bowlby an attachment relationship that provides neither

comfort nor support is likely to arouse anxiety and anger. This may lead to the insecure child's behaving in the peer group "by shrinking from it or doing battle with it" (Bowlby, 1973, p. 208). Children who "shrink" anxiously away from peers preclude themselves from the positive outcomes associated with exploration and peer play. Children who do battle with their peers likely engage in inappropriate exploration and play, thereby leading to rejection and isolation by the peer group.

Attachment theory, then, suggests a number of hypothesis concerning aspects of the quality of children's attachment with caregivers and children's later relationships, including those with peers and romantic partners (e.g., Furman, Simon, Shaffer, & Bouchee, 2002; Kerns, Contreras, & Neal-Barnett, 2000). And indeed, recent research generally supports many of these predictions. A number of studies, for example, have examined the general social orientation and specific social skills of young children with secure and insecure attachment histories. For example, evidence suggests that infants with secure attachment histories are later more popular and socially competent in the peer group during preschool and elementary school than their insecurely attached counterparts (Allen, Moore, Kuperminc, & Bell, 1998; Booth, Rubin, Rose-Krasnor, & Burgess, 2004; Clark & Ladd, 2000; Kerns, Cole, & Andrews, 1998; Schneider, Atkinson, & Tardif, 2001; Simon, Paternite, & Shore, 2001; Sroufe, 1995). Furthermore, there appears to be a contemporaneous association between the security of parent-child attachment, social competence, and peer popularity (Allen et al., 1998; Booth, Rose-Krasnor, McKinnon, & Rubin, 1994; Granot & Mayseless, 2001; Kerns, Klepac, & Cole, 1996). Likewise, research also suggests an association between children's attachment histories and qualities of their contemporaneous and later best friendships and romantic partners (Booth et al., 2004; Freitag, Belsky, Grossmann, Grossmann, & Scheurer-Englisch, 1996; Furman et al., 2002; Hodges, Finnegan, & Perry, 1999; Lieberman, Doyle, & Markiewicz, 1999; Rubin, Dwyer, et al., 2004).

Dimensions of Individual Differences in Adjustment to Peers

Peer social experiences differ in an almost bewildering array of ways across individual children. Elsewhere (Parker et al., 1995; Rubin, Parker, & Bukowski, 1998) we have argued that most attempts to conceptualize variability in children experiences fall into either efforts to repre-

sent children's friendship success, on the one hand, and group acceptance versus rejection, on the other. Although a comprehensive treatment of this issue is beyond the scope of this chapter (see Bierman, 2004; Rose & Asher, 2000; Rubin et al., 1998), a brief overview of the conceptual underpinnings and assessment options in these areas is warranted.

It is important at the outset to acknowledge the distinction between not getting along with peers and displaying troublesome behavior such as aggressiveness toward peers and social withdrawal. Behavioral assessment is one of the oldest traditions of differential child psychology (see, for example, pioneering studies of character by Buhler, 1931; Hartshorne & May, 1929), but behavioral assessments are only indirect assessments of difficulties with peers. As Parker and Asher (1987) proposed a number of years ago, this issue should be understood as the issue of whether measures of *what* the child is like with peers can substitute for measures of *whether* the child is liked by peers. In general, they cannot. Whether peers like a child is manifestly a question about that child's adjustment with peers. Although issues arise about how best to address this question, its status as a question about adjustment with peers is unsailable. Alternatively, whether what a child is like—or how the child behaves—measures adjustment with peers depends partly on the focus of the assessment. Some dimensions of behavioral differences, of course, are irrelevant or presumably only very indirectly indicative of success or failure with peers. Behavior directed toward adults or that is very academically oriented may fall in this category. By contrast, it is difficult to argue that behaviors such as aggressiveness and social withdrawal are not signs of social failure with peers. Even so, the relation between what a child is like and whether a child is liked is an imperfect one, and the task of deciding which behaviors, if any, should be taken as signs of adjustment or maladjustment with peers is a thorny one.

Additionally, a distinction needs to be made between the objective circumstances of children's experiences with peers and children's subjective appraisals, such as their social outlook, motivational orientation to social participation, and attitudes and affect surrounding groups and relationships (Bierman, 2004). Children with objective peer difficulties experience subjective distress over their circumstances. However, children's views of their social success can be widely disparate from their objective circumstances (see Bierman, 2004). Targeting children on the basis of their interpersonal outlook is an important and potentially profitable pursuit in its own right, but should not

be confused with the task of identifying children with objective peer difficulties.

Friendship

Friendship is a subjective relationship and an inherently dyadic construct. Children perceive their friendship partners in particularized rather than role-related ways. They stress the uniqueness of the relationship and reject efforts to treat particular friendship partners as interchangeable with others. Researchers and other observers may note commonalities in personalities or behavioral tendencies across the friendships of a focal child, but the focal child is likely to be impressed by the distinctions and diversity among his or her individual partners and relationships.

These subjective and reciprocal properties are challenges to understanding and require special caution in assessment. For example, to gauge children's group acceptance, other children's affection for the target must be obtained by polling pertinent group members. Conclusions will be misleading if the number of polled members is too small or not representative. But they are not negatively affected by the inadvertent or unavoidable omission of an isolated and particular group member's opinion. Moreover, the focal child need not participate in this assessment. In the assessment of friendship, however, the focal child's perceptions of his or her circle of friends *must* be sought and aligned with independent evidence of reciprocity of affection obtained directly or indirectly from each of these implicated individuals (Asher et al., 1996). Moreover, evidence of reciprocity of affection alone is usually insufficient to presume or substantiate claims of friendship. Children may enjoy each other's company in school but never spend time together outside of school or in other ways have experiences together that lead them to think of each other as friends. Indeed, sometimes children have only limited direct contact with other children they report liking. For example, children can admire another child from a distance, can be grateful to someone who is only an acquaintance, or have affection for someone whose leadership facilitates the group's functioning (Parker et al., 1999). Yet, friendship generally implies that the individuals involved in the relationship not only like or admire one another, but have labeled their relationship a friendship, have some shared history together, are committed to one another, and are comfortable being perceived as a pair of friends by others. Normally, friendship cannot be presumed unless children have been expressly asked whether the relationship in question is a friendship.

There are many diverse, yet nonredundant ways of representing dimensions of differences in friendship experiences among individuals. These include distinctions among individuals in the size and organization of their friendship networks and distinctions among individuals in types of relationship properties that are typical of their friendships.

Friendship Network Size, Density, and Durability

Differences among individuals in friendship network size can be easily and reliably quantified by several techniques (see Bukowski & Cillessen, 1998; Parker et al., 1995). In early childhood, it is common to ask parents or teachers to identify how many friends a child has and perhaps who those partners are (e.g., Gottman, 1983; Howes, 1988). Typically, researchers do not give these informants specific criteria by which the presence of a friendship should be determined. Instead, it is often simply assumed that these informants share the researcher's definition of friendship, which may or may not always be the case. With older children, researchers rely primarily on reciprocal sociometric nomination procedures to assess children's involvement in friendships. Typically, children are presented with a roster or a set of pictures of their same-sex classmates (or some other functionally similar group) and asked to circle or otherwise indicate which members are their best or close friends. The pattern of choices is then examined to identify children who nominate one another. Less often, investigators have used reciprocated high ratings as an index of friendship, either alone or in conjunction with friendship nominations (e.g., Berndt & Hoyle, 1985; Bukowski, Hoza, & Newcomb, 1994). Both procedures are consistent with the requirement that friendship needs reciprocity and is predicated upon affection concerns rather than instrumental issues. When nomination measures explicitly refer to friendship (e.g., "Who are your three best friends?"), they further assure the nominations that surface do so specifically because children have recognized friendship relationships with these individuals (versus some other reason for mutual liking).

Many personal and behavioral traits of children have been reported to be correlated with the size of children's friendship networks (see Parker et al., 1999). Thus, it would appear that the differences children show in the size of their social networks are not haphazard or accidental; instead, size differences appear to reflect differences in individual children's social competence, or, in the very least, differences across children in their preferred manner of relating to others. In most instances, it is the subgroup of children who are friendless that appears to be responsible for these associations (Parker et al., 1999). It is less

clear that children's personal dispositions are the primary determinant of whether children have only a few versus many friends.

A related issue is whether children accrue emotional benefits from participation in many versus only a few friendships. As Parker et al. (1999) point out, it seems unlikely that having one friend would provide children with all of their relationship needs. On the one hand, a child may derive companionship from one friendship and derive intimacy from another friendship. Thus, additional friends should help children meet their interpersonal needs more completely, thereby reducing their loneliness. On the other hand, large friendship networks increase not only the opportunities for social support but also the responsibilities and work necessary to maintain one's relationships (Rook, 1988). Furthermore, large friendship networks may increase opportunities for conflict, jealousy, and rivalry among members of the network. Very limited research exists on this point. Parker and Seal (1996) examined this issue in connection with children's feelings of loneliness. In a study of the evolution of children's social relationships over the course of a month-long summer camp, Parker and Seal assessed the reciprocal friendships of 215 8- to 10-year-old children at several time points. At every point of assessment in the study, children with more friends were less lonely than children with fewer friends. However, when children who were chronically friendless were removed from these analyses, number of friends was not significantly related to children's feelings of loneliness. These results suggest that the ability to predict loneliness from number of friends is largely a function of the distinction between children without friends and children with one or more friends and do not support the commonsense notion that more friends is always better.

In addition to size, children's friendship networks can vary in terms of how close the members are with one another. In dense networks, all of a child's friends are also friends with each other. In less dense networks, particular friendships tend to be isolated from other friendship pairs. To date, research in this area has rarely used network density as an individual-difference variable. Nonetheless, some existing research (e.g., Benenson, 1994; Parker & Seal, 1996) demonstrates that individual children do tend to show reliable differences in the density of their friendship networks. The psychological significance of network density is still an open question, however. Intuitively, a relatively connected, or dense, social network may reduce children's vulnerability to loneliness by fostering a greater sense of community, a greater sense of belonging, and a stronger feeling of security than

a less dense one that pulls children in different, and perhaps competing, directions. Of course, just the opposite may also be the case. It is possible that density contributes to loneliness by heightening the tensions, rivalries, and jealousy of network members. To date, density has been investigated so infrequently that firm conclusions are lacking (Parker et al., 1999).

Finally, some children's friendships tend to be short-lived, whereas other children are clearly capable of sustaining friendships over even very long periods of time. Instability in a network may be reflected in its size, at least when viewed over time. Children's network size can grow over time as new friends are added. Conversely, children who have made many friends may find themselves friendless at some future point if they have difficulty keeping these relationships and difficulty forming new friendships. Accordingly, the trajectory of children's friendship network size over time can augment information that is available through a one-time measurement of size alone (Parker & Seal, 1996).

Friendship Quality

Considering the wide variations in individual characteristics that children bring with them to their friendships, it is reasonable to expect that not all friendships will be alike. Such differences are likely to be related to children's subsequent adjustment, and thus investigators have sought to develop procedures for reliably and validly assessing them. The most common approach involves assessing the features of children's friendships through children's own reports (see Furman, 1996). Assessments of this type are usually conducted with questionnaires or interview procedures, and are predicated on the belief that a child's impression of a relationship is the best index of the quality of this relationship for the child (Furman, 1996).

Although less frequent than self-reports, observational techniques can also be used to study children's relationships with friends. Part of the reluctance of researchers to use observational approaches may stem from the formidable task of isolating the contributions of individual members to the observed patterns of dyadic interaction (Hinde & Stevenson-Hinde, 1976, 1987). This is a very real concern, but some promising observational methods for describing inter-dyad variation have appeared (e.g., Dunn, Cutting, & Fisher, 2002; Lansford & Parker, 1999; Simpkins & Parke, 2002; Youngblade, Park, & Belsky, 1993). Presumably, any interpersonal behavior between friends may be amenable to observational assessments. Researchers have generally been interested in dimensions of

behavior that relate to the putative functions of friendship (e.g., provision of companionship, level of intimate disclosure, degree of helpful advice) or address the affective properties of the relationship (e.g., the affective bonds between friends). Children's conflict and disagreement with friends have also been of interest.

Acceptance versus Rejection in the Peer Group

Children who are liked by most members of a particular group enjoy acceptance in that group. Most children in the group have come to feel that there are many more things to like than dislike about these individuals, and this favorable perception is the prevalent attitude among the members of the group as a whole (Parker et al., 1999). Conversely, when a group rejects children, a consensus has formed among members that a particular child is undesirable, unsuitable, or uninteresting. For their part, children seek affiliation with and develop allegiances to both formal and informal peer groups because inclusion in a group provides a sense of belonging and permits avenues to self-expression and identity development that are not and cannot be cultivated in the context of even the most successful dyadic friendships (Newman & Newman, 2001).

Parker et al. (1999), among others (see Bigelow et al., 1996; Bukowski & Hoza, 1989; Rubin, Bukowski, & Parker, 1998), have stressed the importance of distinguishing friendship success from broader group acceptance. Many members of the group may hold a very positive attitude toward a particular child, but not all may consider that child a friend. Children may enjoy each other's company in school but never spend time together outside of school or in other ways have experiences together that lead them to think of each other as friends. Indeed, sometimes children have only limited direct contact with other children they report liking. For example, children can admire another child from a distance, can be grateful to someone who is only an acquaintance, or may look up to someone for their leadership and facilitation of the group's functioning. Thus, the dimension of group liking/disliking, or group acceptance/rejection specifies the *relation* of a child to a group of peers, but not the child's *relationships* with specific others. Nonetheless, children are no less keenly concerned with status of their relation to significant peer groups than they are with the state of their close friendships.

A wide variety of techniques is available for conceptualizing and assessing children's group acceptance versus rejection status, but far and away the most common procedure

involves sociometric assessment to obtain group members' ratings or nominations of liked and disliked others (see Bierman, 2004; Cillessen & Bukowski, 2000; Parker et al., 1995). Sociometric assessments of group acceptance date at least as far back as Moreno (1934), who pioneered the technique of asking children to nominate liked and disliked other individuals and used the tallies from these surveys to graph sociograms that readily depicted the interpersonal structure of a groups as well as which individuals were popular and which were marginalized or rejected. Moreno's (1934) interest in group dynamics and structure did not leave the same lasting legacy as his interest in the identification of popular and unpopular individuals (but see Bukowski & Cillessen, 1998). Today, Moreno's legacy is most apparent in contemporary assessments of *sociometric status classification* particularly the version formulated and validated by Coie, Dodge, and Coppotelli (1983).

In this procedure, children in a specified group, usually a classroom, are asked to name the 3 to 5 other members they like most and like least. Based on this polling, tallies of the number of positive and negative nominations each member of the group received from all other members are obtained and combined in specific ways to categorized individuals in one of several mutually exclusive and exhaustive status categories. Broadly: Children who receive many "like" and few "dislike" nominations are labeled popular, those who receive many "like" and many "dislike" nominations are controversial. The other categories are rejected (liked by few and disliked by many), neglected (liked by few and disliked by few), and average (often, but not always, all the remaining unclassified children). Recent improvements on this approach, among other things, include efforts to enhance the classification strength of the specific categories (DeRosier & Thomas, 2003).

An alternative sociometric procedure, the *roster-and-rating* rating scale technique (Singleton & Asher, 1977), requires children to rate each of their classmates on a Likert-type scale, according to how much they like or would like to play with the child. Scale points usually range from *Not at all* (1) at the low end to "very much" or "A lot" (5) at the high end. By averaging the ratings that a specific child receives from his or her classmates, the researcher obtains a direct summary measure of the child's acceptance in the group. Researchers also often standardize these ratings within sex and classroom to correct for biases that may exist when children are asked to rate opposite sex classmates and to facilitate the aggregation of data across classrooms (see Bukowski, Sippola, Hoza, & Newcomb, 2000). Sociometric rating assessments offer an especially

attractive alternative to nomination-based procedures with children in middle school or junior high, where it is impractical or inappropriate to define a referent group (such as circumscribed classroom) on which to base social preference and impact scores (e.g., Parker et al., 2005).

Experience with sociometric assessments of acceptance and rejection has led to the conclusion that peer group status is relatively stable over time (e.g., Cillessen, Bukowski, & Haselager, 2000; Hardy et al., 2000; Newcomb & Bukowski, 1984). For example, regardless of the particular sociometric classification system employed, popular children tend to remain popular, whereas rejected children remain rejected (e.g., Brendgen, Vitaro, Bukowski, Doyle, & Markiewicz, 2001). It has been demonstrated consistently that the neglect and controversial categories are the least stable (DeRosier & Thomas, 2003). When changes do occur it is usually from popular to average and vice-versa or from neglected to average. Rarely do popular children become rejected, and even more rarely do rejected children become popular. What is more, the available evidence supports the assertion that an individual's sociometric status classification is not only stable over time in existing groups, but consistent from one group setting to another (see Bierman, 2004).

Stability in group acceptance and rejection is important as it supports researchers' assumptions about why individual children receive the group status they do; namely, that group acceptance or rejection status reflects the social skills and other characteristics of the individual child rather than whimsical or idiosyncratic aspects of the groups in which they find themselves. Nonetheless, progress has been made recently in understanding context, reputation, and other group factors that dictate which children are rejected versus accepted in groups (e.g., Abrams et al., 2003) and it is a mistake to underestimate the role that group level factors play in status emergence and maintenance. Relatedly, researchers have sometimes asked children to nominate peers they *believe* to be popular or rejected in the group. This procedure, then, taps the peer group's *perception* of who is accepted and rejected not their actual acceptance or rejection status. Available evidence cautions against confusing these constructs. Sociometrically and peer-perceived popular individuals are almost wholly distinct groups of individuals (Buskirk et al., 2004; LaFontana & Cillessen, 1999; Parkhurst & Hopmeyer, 1998). Children perceived as popular often are not uniformly positively regarded, and might best be described as controversial (Buskirk et al., 2004; Parkhurst & Hopmeyer, 1998; see also LaFontana & Cillessen, 1999).

DIFFICULTIES WITH PEERS: SHORT- AND LONG-TERM CLINICAL SIGNIFICANCE

Given the many roles that group acceptance and friendship experiences are thought to play in development, it is not surprising that questions of whether and how children's development and well-being are compromised by persistent difficulties with peers. Questions concerning the contributions of peer interaction and friendships to development and those involving the consequences of rejection by peers or other forms of negative peer experiences are obviously related. The better we understand the roles peer experiences play in development the more prescience we can have regarding which children are likely to be at risk for broader adjustment difficulties and which areas of adjustment are likely to be compromised in these children. In actuality, however, studies of the functions of peer experiences in development and studies of the short- and long-term risks associated with peer difficulties have not often been closely connected. Instead, as a rule, clinical child psychologists and psychiatrists are vastly more familiar with the literature on parent-child relationships than the literature on child-peer relationships. Nonetheless, it is probably the case that skilled clinicians are familiar with and, at least intuitively, attentive to disturbances of childhood peer relationships owing to the close connections between difficulties with peers and clinical disorders and subclinical disturbances that bring children to the attention of clinicians. Whether they translate this awareness of peer issues into part of the actual treatment plan would be important to ascertain.

In this section, we consider evidence bearing on the clinical significance of poor peer relationships and children's adjustment. Our treatment here is necessarily brief however and interested readers are directed to our earlier version of this chapter (Parker et al., 1995) as well as a review by Deater-Deckard (2001) for fuller treatments.

Rates of Clinical Referral for Disturbances in Peer Relationships

Estimates of the rates of psychiatric or other referrals specifically for disturbances in peer relationships are difficult to come by. These unknown rates are partly due to the fact that peer problems often accompany other identified problems (e.g., ADHD, disruptive behavior and conduct disorders, anxiety, depression). Nevertheless, the available evidence suggests that poor peer relationships are common reasons for referrals to child specialists. Achenbach and Edelbrock (1981) reported that 30% to 75% of

children (depending on age) referred to child guidance clinics are reported by their mothers to experience peer difficulties (e.g., poor social skills, aggression). Peer difficulties are roughly twice as common among clinic children as among nonreferred children. Similarly, Hutton (1985) examined the records of 215 students referred to school psychologists by teachers in five different school districts. The most common reason for referral for both boys and girls was poor peer relationships. Poor peer relationships were cited as the basis of referral in 26.5% of the children. Moreover, problems of peer adjustment were implied (but not explicit) in other reasons for referral. For example, fighting and shy/withdrawn made up an additional 13.8% and 14.4% of the reasons for referral, respectively.

In an interesting analysis of this issue, Janes, Hesselbrock, and Schechtman (1980) divided a sample of 298 boys and 98 girls seen at a child guidance clinic over a period of years into those with and without poor peer relationships according to assessments obtained from teachers. Because of the way the assessments were conducted, Janes et al. could examine the role that poor peer relationships played in prompting the original clinic referral. Although children having difficulty getting along with peers were sometimes referred to the clinic for this reason, they were more likely to be referred for poor school achievement and behavioral problems at home and school. In other words, difficulties with peers were not likely to prompt a clinic referral unless they were accompanied by other behavior that was (presumably) more worrisome, bothersome, and disruptive to teachers/classrooms and parents. Indeed, only one in eight children identified by teachers as having difficulties with peers was seen at the clinic primarily for that reason. Janes et al.'s findings suggest that clinic referrals may grossly underestimate the prevalence of difficulties with peers unless those difficulties are combined with other difficulties that pose more problems for teachers and parents. Unless peer relationship disturbance comes to be labeled as a separate disorder with its own diagnostic category, these problems will continue to be perceived and conceptualized as secondary in nature.

Comorbidity and Co-Occurrence with Childhood Psychiatric Disorders

Disturbances in peer relationships have traditionally played little formal role in differential diagnosis and psychiatric classification. Notably, there is no formal diagnostic category for disturbed peer relationships in childhood in either the American Psychiatric Association's multi-axial diagnostic taxonomy (*Diagnostic and Statistical Manual, fourth edi-*

tion [DSM-IV], American Psychiatric Association, 1994) or the *Manual of the International Statistical Classification of Diseases* (World Health Organization, 1992).

However, as the *DSM* has been revised, peer relationships gained importance in diagnosing individuals with disorders. For example, in the *DSM-IV*, Axis IV has been restructured so that the clinician records the presence of stress in separate specific classes of stressors rather than giving a global estimate of stress across all possible stressors. Thus, in *DSM-IV*, stressors for social relationships outside the family (e.g., loss of a friend or inadequate social support) are explicitly considered in the diagnostic taxonomy. Peer relationships continue to play a role in specific disorders in a similar manner to that of *DSM-III-R*. However, it is interesting to note that the Pervasive Developmental Disorders have been expanded to include three new classifications of disorders where a primary symptom is the child's inability to engage in appropriate social interaction (i.e., Rett's Disorder, Asperger's Disorder, and Childhood Disintegrative Disorder; see *DSM-IV*). Of particular interest is Asperger's Disorder for which chronic, severe impairment in social interaction, communication, and behavior (without the language, cognitive, and self-help skill delays seen in Autism) are the essential diagnostic features.

Problems of peer adjustment also appear prominently in the makeup of most dimensions of maladjustment arising from the behavioral assessment approach. Some measures contain subscales or content, which attends to the child's success or failure in the interpersonal realm. For example, the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1986) identifies two broad dimensions of child functioning—internalizing problems (inhibition, shy-anxious behavior) and externalizing problems (acting out, aggressive behavior)—as well as several more specific (i.e., narrow) dimensions of functioning (e.g., anxiousness, schizoid behavior, sleep disturbances, aggressiveness). Peer relationship problems are reflected in several of the items (e.g., "poor peer relations," "bad friends") that make up both the broad-band and narrow-band subscales of this measure. The New York Teacher Rating Scale (NYTRS; Miller et al., 1995), which assesses oppositional defiant disorder and conduct disorder, includes a peer relations subscale. This subscale includes items such as "helpful to others" and "has at least one good friend." A high score on this subscale reflects better functioning. The Autism Diagnostic Interview-Revised (ADI-R; Lord, Rutter, & LeCouteur, 1994), the Children's Depression Inventory (CDI; M. Kovacs, 1981), Reynolds Adolescent Depression Scale (RADS; Reynolds, 1986), and Anxiety Disorders Interview

Schedule for *DSM-IV*-Child Version (ADIS-IV-C; Silverman & Nelles, 1988) all contain content that assesses interpersonal relationships.

The Peer Relationships of Children with Psychiatric Disorders

Though peer problems clearly play a role in the diagnosis of psychiatric disorders, the peer relationships of children with specific psychiatric disorders have received substantially less interest compared to normal and distressed, but subclinical, populations of children. Therefore, relatively little is known about the type and quality of peer interactions and the impact of those interactions on the emergence and maintenance of psychiatric/psychological disorders. Prospective studies of psychiatric disorders with low prevalence rates are difficult to achieve and costly, particularly in light of the fact that sociometric assessments are the most common and most defensible methodologies for assessing adjustment with peers, and these techniques require large numbers of informants (e.g., most peers within the same grade at school)—clearly a method that is impractical for clinical settings. The use of clinical samples is more feasible, but because the disorder has emerged, this research is limited in its ability to assess premorbid developmental trends. With this in mind, several specific psychiatric disorders of childhood and adolescence are discussed next in relation to their association with peer relationship problems.

Attention Deficit/Hyperactivity Disorder

The diagnosis for Attention Deficit/Hyperactivity Disorder (ADHD) does not include problematic peer relationships as an essential symptom; however, some researchers have argued that interpersonal difficulties should serve as a defining characteristic (Landau & Moore, 1991; Whalen & Henker, 1991). Almost half of ADHD children have significant peer relationship problems (Guevremont & Dumas, 1994). Children with ADHD display large social skills deficits, often seen as intrusive, loud, annoying, and generally aversive by their peers (see Landau & Moore, 1991). In addition, there is evidence that the social reasoning of ADHD children may be more negative. For example, Whalen and Henker (1991) compared 25 ADHD and 14 normal boys ages 6 to 12 and found that the ADHD boys saw their peers in a more negative way, identifying more undesirable behaviors in peers than did the non-ADHD boys. Overall, ADHD children have been found to be more likely to experience disturbed peer relationships and rejection by peers (Landau & Moore, 1991).

A further complicating factor is the high degree of comorbidity of ADHD with other psychiatric diagnoses, particularly the other Disruptive Behavior Disorders (i.e., Conduct Disorder and Oppositional and Defiant Disorder; August, Ostrander, & Bloomquist, 1992; Barkley, Anastopoulos, Guevremont, & Fletcher, 1991) and Learning Disorders (LD; Flicek, 1992). This comorbidity may additionally contribute to peer disturbances. For example, in a study of 249 2nd through 6th graders, Flicek (1992) found that children with both ADHD and LD were most likely to be rejected and displayed the most disturbed social behavior compared to all other children.

Children with ADHD are frequently treated with stimulant medication, particularly methylphenidate (Ritalin). Results indicate that treatment with Ritalin improves the social interactions, through decreasing aversive behavior, and enhances the social status of children with ADHD (Whalen & Henker, 1991).

Conduct Disorder

As with ADHD, children with Conduct Disorder (CD) tend to have very problematic peer relationships and to be highly disliked or rejected by their peers (e.g., Hinshaw & Lee, 2003). However, unlike ADHD, the primary peer difficulty in CD tends to be aggression. Rather than being simply intrusive, irritating, and overbearing to peers, CD children tend to bully and otherwise aggress toward peers, to intimidate and victimize peers, and to violate the rights of peers (e.g., steal, lie, or destroy property).

It is hypothesized that CD children experience early maladaptive patterns of reinforcement for aggressive behavior as well as exposure to hostile role models, resulting in a hostile, self-defensive view of the world; so that, in the end, aggression becomes the response of choice to deal with interpersonal situations (Dishion & Kavanagh, 2003). Aggression can be a very effective tool for achieving goals and for controlling the behavior of others, but it also increases the likelihood that others will reciprocate the aggression. This pattern develops into a self-perpetuating negative cycle between the child and the social context whereby both the child's aggressive behavior and his or her self-defensive view of the world are continually reinforced and maintained (Coie & Dodge, 1998).

In longitudinal studies, peer rejection in early and middle childhood predicts conduct problems in late childhood and adolescence (Coie, Terry, Lenox, Lochman, & Hyman, 1995; Kraatz-Keiley, Bates, Dodge, & Pettit, 2000; Miller-Johnson, Coie, Maumary-Gremaud, Bierman, & Conduct Problems Prevention Research Group, 2002), and there is some evidence that peer rejection may

play a causal role in the development of CD (Patterson, Capaldi, & Bank, 1991). When aggressive children are rejected from the broader peer group, they tend to associate with other aggressive and rejected peers (Espelage et al., 2000, 2003; Gest, Farmer, Carins, & Xie, 2003; Kiesner, Poulin, & Nicotra, 2003; Xie, Cairns, & Cairns, 1999). Involvement in a deviant peer group exposes them further to deviant models and restricts their opportunities to interact with nondeviant peers. Furthermore, deviant peers may reinforce delinquent acts through their positive responses to deviant behavior (Bagwell & Coie, 2004; Dishion, Eddy, Haas, Li, & Spracklen, 1997; Dishion et al., 1996; Dishion, McCord, & Poulin, 1999). Involvement in deviant peer groups has been found to be predictive of adolescent substance use, disruptive behavior, and delinquency (Dishion, Capaldi, & Yoerger, 1999; Dishion & Owen, 2002; Keenan et al., 1995) as well as early school dropout (Cairns, Cairns, & Neckerman, 1989). Thus, peer rejection may set in motion an escalating cycle toward conduct disorder.

In *DSM-IV* (1994), there are two subtypes of CD: Childhood Onset Type (i.e., before age 10) and Adolescent Onset Type (i.e., between ages 10 and 18). Children with Childhood Onset CD experience more disturbed peer relationships and are more likely to have persistent CD throughout adolescence and develop Antisocial Personality Disorder in adulthood (*DSM-IV*, 1994; Hinshaw, Lahey, & Hart, 1993; Hinshaw & Lee, 2003). In contrast, children with Adolescent Onset CD tend to display less aggressive behavior and to have more normative peer relationships (*DSM-IV*, 1994; Hinshaw et al., 1993).

Pervasive Developmental Disorders: Autism, Rett's, Childhood Disintegrative, and Aspergers

Unlike the previous two disorders, the primary symptom related to peer relationships for the Pervasive Developmental Disorders (PDD) is social functioning impairment (Barnhill, 2001). Autism and Asperger's Syndrome are, in large part, defined by the child's inability to engage in age appropriate social interactions (*DSM-IV*, 1994). Rett's and Child Disintegrative Disorder include a loss of social engagement and social skills from a previously normal developmental level and are associated with severe or profound mental retardation. Children with Autism and Asperger's Syndrome prefer solitary activities and have great difficulty forming and maintaining friendships. They may be completely unresponsive to and detached from social relationships, interacting with others in a nonemotional, instrumental way. In addition, their social sensitivity or

awareness of the thoughts and feelings of others may be severely limited.

Asperger's children are aloof and have aggressive tendencies (Barnhill, 2001). Research has suggested that the reason children with Asperger's Syndrome act aggressively is that they have trouble interpreting social intentions, encoding conflicts and cues, and choosing problem-solving strategies (Carothers & Taylor, 2004).

Children with Autism (but not Asperger's Syndrome) also have language (delay or absent), communication (e.g., difficulty initiating a conversation), and cognitive impairments (e.g., approximately 75% of children with Autism also have Mental Retardation; *DSM-IV*, 1994). Their language is often repetitive, stereotyped, and idiosyncratic. Research indicates that when children with Autism avoid social interaction, this avoidance predicts subsequent peer avoidance and language use (Ingersoll, Schreibman, & Stahmer, 2001).

Recent research has addressed the peer interactions of children with Autism. For example, they tend to make fewer social initiations even when compared with peers who have other developmental disabilities (Sigman & Ruskin, 1999). Very few children with Autism have friendships with same-age peers (Orsmond, Krauss, & Seltzer, 2004). Those who do have friends report a lower quality of companionship in those friendships (Bauminger & Kasari, 2000).

Anxiety Disorders

Anxiety disorders are among the most common psychological disorders of childhood and adolescence (Albano, Chorpita, & Barlow, 2003; Beidel, 1991). Children who are anxious tend to remain anxious through adolescence and adulthood, even though they may no longer meet the diagnostic criteria for an anxiety disorder (Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1995; Last, Perrin, Hersen, & Kazdin, 1992). Although several anxiety disorders are associated with impaired peer relationships, developmental models of social anxiety, in particular, have implicated limited social interaction and poor peer relationships (Rubin & Burgess, 2001). For example, young children with certain temperamental vulnerabilities, such as behavioral inhibition, experience psychological and physiological discomfort in social situations, which may place them at risk for the development of social anxiety. Withdrawal from social interaction during early childhood limits important socialization opportunities, and thereby may impede the development of social skills. Social skill deficits may then elicit negative peer reactions, which, in turn, perpetuate further social withdrawal and increase so-

cial anxiety (Rubin & Burgess, 2001; Rubin, Burgess, Kennedy, & Stewart, 2003). This cycle may be sustained and strengthened if anxiety decreases as a result of social avoidance because such negative reinforcement increases the likelihood of subsequent avoidance and withdrawal (Rubin, Burgess, & Coplan, 2002).

The majority of shy, withdrawn, and anxious children report having mutual friendships (Schneider, 1999; Wojslawowicz, Rubin, Burgess, Rose-Krasnor, & Booth, in press). However, the friendships of these children are relatively lacking in fun, intimacy, helpfulness and guidance, and validation and caring (Rubin, Wojslawowicz, Burgess, Rose-Krasnor, & Booth, 2004; Wojslawowicz et al., in press). Other studies indicate that social anxiety is associated with peer rejection (Inderbitzen et al., 1997) and peer victimization (Craig, 1998; Vernberg, Abwender, Ewell, & Beery, 1992). Several other anxiety disorders and multidimensional measures of anxiety have also been linked with peer problems (e.g., Grills & Ollendick, 2002).

Depression

Although deficiencies in social relationships are not required for the diagnosis of depression, current conceptualizations of the etiology and maintenance of depressive symptoms emphasize the role of social skills and dysfunctional interpersonal behavior (e.g., Joiner, Coyne, & Blalock, 1999). Children lacking in social support are believed to be at an increased risk for depression (Windle, 1992). The absence of involvement in friendship undermines self-esteem and deprives children of important pleasurable experiences, contributing to the development of depressive symptomology. Because friends also may be important in buffering children against stress, the presence of close satisfying relationships with friends could be expected to protect children from depressive affect in connection with stress (Windle, 1992). Peer relationships have been found to protect adolescents against depressive symptoms more than parental relationships (I. Hay & Ashman, 2003).

The available literature is generally supportive of a link between depression and difficulties with peers (e.g., Craig, 1998; DiFilippo & Overholser, 2000; Hammen & Rudolph, 2003; Kistner, Balthazor, Risi, & Burton, 1999; Prinstein, Boergers, Spirito, Little, & Grapentine, 2000; Vernberg, 1990). In an interesting study of this issue, Vernberg, for example, found that among young adolescents, less closeness with a best friend, infrequent contact with friends, and more experiences of victimization by peers contributed to increases over time in depressive affect. Likewise, in a 5-

year longitudinal study of young boys, Cillessen, Van Lieshout, and Haselager (1992) found the experience of peer rejection led to higher levels of loneliness, which in turn increased the risk for developing depression. In their meta-analysis, Hawker and Boulton (2000) also reported links between peer victimization and several internalizing problems, including depression, anxiety, loneliness, and poor self-esteem. Depressed children tend to perceive their own status more negatively than their peers do (Cole, Martin, Peeke, Seroczynski, & Hoffman, 1998), view themselves as less accepted by their peers (Brendgen, Vitaro, Turgeon, & Poulin, 2002), and report a lower friendship quality with their best friends (Brendgen et al., 2000) compared with nondepressed children.

On the other hand, there is also support for the view that depressive affect contributes to problems with peer relationships (Joiner et al., 1999), possibly because peers make unflattering generalizations about other children's behavioral characteristics in the face of evidence of depressive affect (Peterson, Mullins, & Ridley-Johnson, 1985). A number of other factors provide further explanation for depressed children/adolescents' problematic peer relationships, including depressed children's difficulty handling conflict with peers, more emotional dysregulation during stressful peer interactions, and depressed youths' tendency to seek excessive reassurance from peers (Hammen & Rudolph, 2003).

Less evidence is available concerning the protective role of friendships in relation to depression. Based on their review of the literature, Peterson et al. (1993) concluded that good peer relationships in early adolescence do not appear to provide a protective influence; later in adolescence, close peer relationships do appear to be protective, particularly when parent relationships are impaired in some way (Peterson, Sarigiani, & Kennedy, 1991). However, depressed children with high-quality friendships may also be at risk. Recent research indicates that close friends who spent excessive amounts of time ruminating over problems (called co-rumination) are at risk for greater internalizing symptoms like depression (Rose, 2002). Girls reported more co-rumination than did boys. These findings may help explain why girls report higher levels of depressive symptoms.

Eating Disorders

The *DSM-IV* identifies Anorexia Nervosa, Bulimia Nervosa, and eating disorder not otherwise specified (EDNOS) as eating disorders. Few young children meet the *DSM* guidelines for diagnosis of an eating disorder, but many children present subclinical variations of them

(Bryant-Waugh & Lask, 1995). Children who participate in activities in which weight is a main focal point (i.e., ballet, wrestling, gymnastics) may be especially prone to developing eating disorders (Garner, Rosen, & Barry, 1998).

Recent work focusing on how children and adolescents develop disturbances in their body image and eating-related concerns has found that peers may play an important role. Oliver and Thelen (1996) examined eating concerns in children in 3rd through 5th grade. They found that children's perceptions of peer influence were associated with their eating and body image concerns. Girls were more likely than boys to believe that being thin would increase their likeability among peers, although both boys and girls viewed appearance as being related to their peer acceptance. Phares, Steinberg, and Thompson (2004) also found that girls were more concerned with eating and body image than boys. In their sample of elementary school children, they found that both boys and girls who expressed higher levels of dissatisfaction with their bodies also reported higher levels of depressive symptoms and lower levels of self-worth. Furthermore, they found that girls were more active in attempts to become or remain thin.

Loneliness and Subjective Distress

As noted, Sullivan (1953) attached considerable significance to loneliness as a motivational force in development and adjustment. At the same time, Sullivan was pessimistic about the promise of measuring loneliness with any precision:

Now loneliness is possibly most distinguished, among the experiences of human beings, by the toneless quality of the things said about it. . . . I, in common apparently with all denizens of the English-speaking world, feel inadequate to communicate a really clear impression of the experience of loneliness in its quintessential force. (pp. 260–261)

His own pessimism notwithstanding, research does suggest that loneliness is tractable to scientific study and supports Sullivan's claims about the circumstances that give rise to loneliness and its significance as a motivational force in development (see Rotenberg & Hymel, 1999). Of particular interest, research supports an association between difficulties with peers and children's feelings of loneliness. Most research, to date, has focused on loneliness and children's group acceptance. Problematic group acceptance appears robustly associated with loneliness. This is true whether acceptance is measured with a sociometric rating-scale measure (e.g., Parker & Asher,

1993; Parker & Seal, 1996; Quay, 1992; Renshaw & Brown, 1993) or with sociometric nominations that classify children into different sociometric status groups. In the latter case, the evidence shows that rejected sociometric status is associated with greater feelings of loneliness and social dissatisfaction in early adolescence (Boivin & Hymel, 1997; Boivin, Hymel, & Bukowski, 1995; Boivin, Poulin, & Vitaro, 1994; Crick & Ladd, 1993; Parkhurst & Asher, 1992; Sanderson & Siegal, 1995; Sletta, Valas, Skaalvik, & Sobstad, 1996), during middle childhood (e.g., Crick & Ladd, 1993), and during early childhood (Cassidy & Asher, 1992). Neglected sociometric status has not been found to be associated with risk for loneliness. Furthermore, this pattern has been found not only in school contexts (the context that characterizes virtually all research conducted in this area) but in a summer camp context as well (Parker & Seal, 1996). In addition, this relation has now been obtained in several countries (e.g., Australia, Canada, the Netherlands, Norway, and the United States). Also, loneliness does not appear to be an experience that unpopular children can easily shed by changing their activities or social settings. Asher et al. (1996) queried children about their loneliness in a variety of school contexts (i.e., the classroom, physical education, lunchroom, and recess on the playground); Regardless of the activity context they were asked to consider, rejected children reported greater levels of loneliness than better accepted children. Finally, Cillessen, van Ijzendoorn, Van Lieshout, and Hartup (1992) reported that the links between the experience of peer rejection and levels of loneliness hold up longitudinally, and may be implicated in the development of depression. Importantly, it has been found that rejected/withdrawn children report more loneliness and social detachment than popular children or children who are rejected but aggressive (e.g., Gazelle & Ladd, 2003). These relations have been reported throughout childhood and early adolescence (e.g., Crick & Ladd, 1993; Parkhurst & Asher, 1992). Further, one can find a consistent link between peer victimization and loneliness (Boulton & Underwood, 1992; Kochenderfer & Ladd, 1996). Indeed, abusive peer interactions have been found to be antecedent to children's loneliness rather than a concomitant or consequence (Kochenderfer & Ladd, 1996).

Focusing on friendship indices rather than sociometric status, Parker and Asher (1993) reported that elementary school-age children without friends are lonelier than other children. Interestingly, this relation between loneliness and having a friend held for children at all levels of group acceptance, suggesting that popularity and involvement in

friendships contribute additively rather than interactively to feelings of loneliness (see also Nangle, Erdley, Newman, Mason, & Carpenter, 2003). Parker and Asher also examined the relation between loneliness and six qualitative features of children's closest friendships—levels of companionship, conflict, conflict resolution, intimate disclosure, help and guidance, and personal validation. Loneliness was found to be strongly, albeit redundantly, associated with each of these six aspects of friendships. Once again, these effects were independent of the contributions of peer acceptance. For young children as well, the evidence thus far indicates that the quantity (large friendship network) and quality of friendships decrease feelings of loneliness and subjective distress due to the supportive provisions offered by this peer relationship (Burgess et al., 2005).

Poor Childhood Peer Relationships and Later Adult Adjustment

Interest in the implications of problematic relationships with peers for children's long-term behavioral and psychological adjustment dates to the earliest days of research on children's peer relationships. Indeed, the premise that children with relationship problems are at risk for later life difficulties is one of the most widely shared professional and popular beliefs about development and psychopathology and has played an important role in motivating research on children's adjustment with peers. In this section, we offer a brief overview of the basis for this conclusion. Readers interested in a more complete treatment are referred to our earlier version of this chapter (Parker et al., 1995), and reviews by Bierman (2004), Hawker and Bolton (2000), Rubin, Hastings, Chen, Stewart, and McNichol (1998), Nangle and Erdley (2001), Schneider (2000), and Deater-Deckard (2001). Further, while the existence of such long-term linkages has enjoyed almost universal acceptance, opinions diverge surrounding the causal basis of this presumed association (e.g., Vernberg, 1990). We return to this question in the following section.

In general, available data do provide compelling evidence of a link between problematic peer experiences in childhood and children's risk for subsequent mental health difficulties (e.g., Booth et al., 1994; Brendgen et al., 2001; Burks, Dodge, & Price, 1995; Cairns et al., 1989; Coie, Lochman, Terry, & Hyman, 1992; Coie et al., 1992; DeRosier, Kupersmidt, & Patterson, 1994; Kochendorfer-Ladd & Waldrop, 2001; Kupersmidt & Coie, 1990; Ladd & Burgess, 2001; Ladd & Troop-Gordon, 2003; Olweus,

1993). This conclusion rests in part on numerous studies that document differences in the peer relationship histories of disordered versus nondisordered adults. Illustrative of this approach and general finding is a series of pioneering studies by Roff published in the late 1950s and early 1960s (Roff, 1957, 1960, 1961, 1963). Roff searched military service records to locate servicemen who, in middle childhood, had been referred to one of two guidance clinics in Minnesota and who later showed problematic military adjustment in the form of either a diagnosis by military psychiatrists as neurotic (Roff, 1957, 1960) or psychotic (Roff, 1961) or received a dishonorable discharge for antisocial conduct (Roff, 1963). The child clinic records of these servicemen were then reviewed for evidence of earlier difficulties with peers (e.g., dislike by the general peer group, inability to keep friends, and being regarded as odd, peculiar, or queer by other children) and compared with those of former clinic patients who had exemplary later military service records. Results indicated a strong association between disorder and poor childhood peer relationships. Specifically, about half of all neurotic servicemen had shown poor peer adjustment when seen at the clinic in childhood compared to only one in eight normal servicemen. Similarly, about two-thirds of the psychotics, but only one-fourth of the normals, had shown poor peer adjustment. Finally, twice as many of the servicemen dismissed for antisocial conduct had shown poor peer adjustment as control servicemen (54% versus 24%, respectively). In short, depending on the psychiatric or behavioral disorder, disordered servicemen were anywhere from 2 to 4 times as likely as nondisordered servicemen to have had a history of poor peer relationships.

Roff's findings are consistent with those of other researchers employing this type of case-control or follow-back design in which child guidance clinic files or other archival data are reviewed for groups of adults who are known to be psychiatrically disordered versus nondisordered. Moreover, this pattern is not limited to adults with serious psychiatric disorders, but is also characteristic of juvenile delinquents, dropouts, and high school students who do poorly academically and socially. Further, this finding is relatively unaffected by changes in methods of collecting childhood peer data because it occurs in studies that use retrospective interviews, studies that abstract guidance clinic records, and studies that use school records. Childhood peer adjustment variables under some circumstances may even distinguish disordered from nondisordered adults when many other intellectual and demographic variables do not (e.g., Cowen et al., 1973).

Despite the consistency of their conclusions, as a group the results of these studies have raised concern owing to their reliance on follow-back designs. Case-control or follow-back studies are useful for suggesting connections between adult symptoms and childhood behavior, but cannot provide data interpretable in terms of predictive risk. That is, case-control approaches do not address whether children with a certain level of type of acceptance, when compared with others with higher or more adaptive types of acceptance, have an increased likelihood of experiencing later maladjustment. Such probabilistic prediction is possible only from cohort prospective studies that first identify samples of peer adjusted and nonadjusted children and then follow these children over time to determine the proportion in each of these two groups who subsequently develop disorder. This reduces the possibility of overestimating the importance of a particular childhood characteristic (such as peer rejection) in the etiology of a subsequent disorder.

Follow-up studies are expensive, inflexible, and may require decades to complete. Moreover, to ensure that a sufficiently large number of individuals later develop some specific disorder, peer adjustment data must ideally be gathered on a large number of individuals in childhood. For these and other reasons, there are fewer prospective than case-control studies linking early peer adjustment to later outcomes. Like their counterparts, however, these studies provide compelling evidence of a link between problematic peer experiences in childhood and children's risk for subsequent mental health difficulties (e.g., Ladd & Burgess, 2001; Ollendick, Weist, Borden, & Greene, 1992; Woodward & Fergusson, 1999). Research indicates, for example, that peer relationship problems, especially peer rejection, are associated with increased rates of internalizing symptoms, such as anxiety and depressive symptoms (e.g., Coie et al., 1995; Gazelle & Ladd, 2003; Kraatz-Keiley et al., 2000). Links have also been found between early peer relationship difficulties and various forms of externalizing difficulties, including involvement in juvenile and adult criminal behavior. For example, Woodward and Fergusson (1999) found that children (age 9) with peer relationship problems were at increased risk for later criminal behavior, substance abuse, and suicidal behavior by age 18, although they were not at increased risk for depression or anxiety disorders.

As another example, Ollendick et al. (1992) identified sociometrically rejected, neglected, popular, controversial, and average status in a large sample ($n = 600$) of 9-year-old children and followed them for 5 years, documenting the incidence of subsequent academic, delinquent, behavioral, and

psychological disturbance. Ollendick et al.'s findings strongly supported the risk status of rejected children. At 5-year follow-up, rejected children were perceived by their peers as less likable and more aggressive than popular children. Rejected children were also perceived by their teachers as having more conduct problems, aggression, motor excesses, and attention problems than their popular counterparts. Moreover, rejected children reported a more external locus of control and higher levels of conduct disturbance and substance abuse, performed less well academically, failed more grades, and were more likely to drop out of school and to commit delinquent offenses than the popular children. Clearly, rejected children were at risk when compared with popular children. Furthermore, rejected children differed from average children on most of these same measures, including failed grades, dropping out of school, and commission of delinquent offenses. Thus, it cannot be said that they differed only from a very well accepted group; rather, they also differed from the average child in the class. A similar pattern was evident for controversial children. Controversial children differed from popular and average children on most of the academic, behavioral, and social measures. In fact, they were similar to rejected children on most measures. For example, a similar number of controversial children (27.3%) as rejected children (33.3%) failed at least one grade and the children in the two groups committed similar numbers of delinquent offenses. Neglected children did not differ from average children on any measure and differed from popular children only on the locus of control and peer evaluation measures.

Overall, the pattern of findings from studies using both follow-back and prospective designs are consistent with the conclusion that early difficulties with peers place children at risk for subsequent, sometimes serious, disorders. This finding emerges not only from studies employing clinic samples, but also from studies of school samples as well. Further, peer difficulties have been implicated in risk for a wide range of significant outcomes, including general mental health problems, externalizing and internalizing symptoms, juvenile and adult criminality, substance abuse, school difficulties and dropping out, and severe psychopathology. We turn next to the presumed causal basis of this association.

Understanding the Link between Poor Peer Relationships and Later Adjustment Problems

Our review indicates considerable support for a link between early difficulty with peers and maladjustment later in life. How can this link be understood?

Simple Incidental and Causal Explanations

Previously, we (Parker et al., 1995) offered a characterization and critique of two alternative interpretations of the link between poor peer relationships and later personal adjustment. Both positions represent attempts to understand the links over time between deviant behaviors and problems relating to peers, with subsequent academic, behavioral, and psychiatric disturbances. The interpretations differ, however, in the extent to which they view problems in adjustment to peers as tangentially or centrally (i.e., causally) involved in the etiology of the later difficulties.

The first, or incidental, interpretation makes no assumption that problems with peers cause the interpersonal and intrapersonal difficulties they later predict. Instead, an association between these variables exists because behavioral precursors and subclinical symptoms of later disorders and deviancies perturbed peer relationships early on. As we have seen, there is considerable comorbidity between mental health disturbances and maladjustment with peers in childhood, and children respond negatively to the flat affect and social withdrawal that characterizes depressed children, for example. Disturbances in peer relationships may make particularly good red flags for later disorder, but there is no assumption that poor peer relationships make any independent contribution to later maladjustment and no reason to suspect that children who are rejected by peers for reasons other than underlying disorder will have later maladjustment.

A schematic representation of the extreme incidental view of peer disturbances and later maladjusted outcomes is shown in Figure 12.1. The model presupposes an underlying disposition to later psychopathology. This disposition may be constitutional (e.g., a biological diathesis) or derive from early environmental influences (e.g., poor early parenting or maltreatment resulting in insecure attachment) or some process of coacting constitutional and environmental factors—

Figure 12.1 Simple incidental model of the link between peer relationship problems and later disorder. Notes: PPR = Problems in peer relationships; MB = Maladaptive behavior toward peers. Adapted from "Peer Relations and Later Personal Adjustment: Are Low-Accepted Children at Risk?" by J. G. Parker and S. R. Asher, 1987, *Psychological Bulletin*, 102, pp. 357–389.

its origins need not concern us here. The important feature is that this pathogenic process unfolds over time, resulting eventually in disordered outcome. The child's peer relationships are disrupted along the way (upward arrows) by the negative behavioral manifestations of the underlying pathogenic process. One might suppose that, because of reputation or other factors, these disruptions make it less likely for children to establish satisfactory peer relationships over time. However, the important influence is the underlying pathogenic process that disrupts behavior, and the peer disruptions themselves are epiphenomenal to the later maladjustment.

The alternative extreme position attributes later disturbance directly to the experience of earlier disruptions in peer relationships. Owing much to the developmental task framework, this causal position holds that many later disturbances can be traced to children's failure to establish effective and positive relationships with peers in childhood and adolescence. Because they are deprived of the important socialization experiences that positive peer interaction affords, and because they lack important sources of social support, children with peer difficulties experience more stress, have less mature and flexible social and cognitive skills, have less well-developed moral reasoning and less commitment to conventional behavior, are less socialized generally, and have more idiosyncratic patterns of thought and behavior. These factors leave them less capable of meeting social responsibilities and expectations; less able to form subsequent, satisfactory interpersonal relationships; and more vulnerable to stress and breakdown.

A schematic representation of the extreme causal position appears in Figure 12.2. Again, some hypothetical representative time points appear along the X-axis, and the relations among problems with peers, behavioral problems, and later maladjusted outcome are shown. In this instance, maladjustment is shown as the result of the cumulative

Figure 12.2 Simple causal model of the link between peer relationships problems and later disorder. Notes: MB = Maladaptive behavior toward peers; PPR = Problems in peer relationships. Adapted from "Peer Relations and Later Personal Adjustment: Are Low-Accepted Children at Risk?" by J. G. Parker and S. R. Asher, 1987, *Psychological Bulletin*, 102, pp. 357–389.

experience of peer ostracism and failure rather than as the unfolding of an underlying pathogenic process. Note that the process of disruption begins with signs of maladaptive behavior with peers. The model is silent on the issue of the origins of this maladaptive behavior, although it is not incompatible with the argument that unspecified constitutional and early experiential factors contribute to original behavioral problems that, in turn, contribute to the development of problems with peers. Otherwise, like the incidental model, the causal model assumes that problematic behavior influences and maintains problems with peers at all ages (upward arrows) and has its own momentum (horizontal arrows).

Few studies have directly pitted causal and incidental explanations in the prediction of later maladjustment, and, indeed, because of the complexity of each explanation, it seems unlikely that any single study could do so effectively. An important prerequisite for accepting a causal model is evidence that poor peer relationships have a significant, negative impact on later maladjustment beyond the influence of child characteristics, such as behavioral style. In recent years, covariance multivariate models and cross-lagged stability models have been exploited to examine this issue, and indeed this work indicates that peer rejection contributes uniquely to multiple forms of later adjustment problems, including internalizing and externalizing symptomatology and declines in academic performance (Ladd & Burgess, 2001; Miller-Johnson, Coie, Maumary-Gremaud, Bierman, & Conduct Problems Prevention Research, 2002; Miller-Johnson, Coie, Maumary-Gremaud, Lochman, & Terry, 1999; Wentzel, 2003). Insofar as these findings suggest that peer problems are not simply a marker of a pathogenic process, a strictly incidental explanation for these linkages seems inadequate.

Interactional and Transactional Interpretations

Incidental and causal views are caricatures and not likely to be steadfastly held by many actual authors. Even so, these models have exerted an influence on how researchers conduct and interpret longitudinal research on the long-term sequelae of early problems (see Parker & Asher, 1987). Importantly, neither view is likely to prove satisfactory to explain the link between problems with peers and later adjustment. As Parker and Asher (p. 379) observed:

The extreme incidental model seemingly denies the very real possibility that the experience of peer rejection, especially prolonged peer rejection, leads a child to view the world and him- or herself negatively. . . . Ongoing rejection by peers must negatively affect many aspects of the child's social, aca-

demic, affective, and moral development. . . . Alternatively, an extreme causal view ignores the fact that factors that antedate poor interpersonal relationships continue to play a role in subsequent outcomes. It seems likely that factors that contribute to poor peer adjustment also continue to shape the course and nature of subsequent adjustment.

More generally, students of developmental models will recognize the incidental and causal views above as specific instances of main effects models emphasizing the contributions of the child or environment, respectively (Sameroff & MacKenzie, 2003). According to the incidental model, information concerning the child's constitutional nature is sufficient to accurately predict later outcomes. Likewise, the causal model implies that, while characteristics of the child, such as aggressive or withdrawn behavioral styles, may contribute initially to peer rejection, subsequent peer interactions and socialization processes are responsible for later maladjustment. Missing from both models is any appreciable attention to (1) how characteristics of the child might condition the impact of ostracism by peers and (2) how rejection by peers contributes to what is characteristic of the child.

In other areas of psychology, interactional models have proven useful for understanding the conditional impact of environmental events on development (Sameroff & MacKenzie, 2003; Wachs, 1992). The diathesis-stress model is an example of an interactional model that is frequently drawn on in the study of developmental psychopathology (Garmezy, 1974). In this view, every child has a particular genotypic profile that defines its constitutional vulnerability to disorder. However, this genotypic vulnerability has to be activated by an environmental stressor in order for the disorder to be manifested. The impact of a particular stressor is not invariant across individuals. Rather, whether a stressor produces maladjustment depends on the child's particular constitutional make-up. A low level of stress may produce disorder for children whose genotypic vulnerability is high, but not for other children. Similarly, an extremely stressful event may produce disorder in almost all children, except those with a very low level of vulnerability. Thus, an interactional model, such as the diathesis-stress model, states that developmental outcomes can be predicted only when the interaction between child and environmental influences are taken into account.

As we noted earlier, in the study of peer relationships, very little longitudinal work has examined whether the combination of child characteristics, such as behavioral or social-cognitive style, and peer rejection places children at differential risk for later maladjustment. Several lines

of research suggest, however, that there are considerable differences in the behavioral and social-cognitive profiles of low-accepted children and that considering both child and social influences may greatly enhance the predictability of disorder, both in general and of specific types (e.g., Bierman, Smoot, & Aumiller, 1993; Kuper-smidt & Coie, 1990). For example, in a classic study of 95 6- to 12-year-old boys, Bierman and colleagues found that peer-rejected children who also displayed excessive aggressive behavior were most likely to exhibit severe conduct problems, whereas children who were rejected but not aggressive were most likely to exhibit passivity.

Although an interactional interpretation addresses the need for a more conditional understanding of the impact of poor peer relationships on later adjustment, it falls short of being a comprehensive model of this process, one which allows for feedback among the causes of problems with peers, the consequences of poor peer relationships, and the course of later maladjustment. In other words, we are lacking a transactional model (Sameroff & MacKenzie, 2003) of the link between difficulties with peers and later adjustment. Transactional models have been extremely helpful for conceptualizing and understanding a variety of phenomena in other areas, including Schizophrenia (Barocas & Sameroff, 1982), community violence, child maltreatment (Cicchetti & Lynch, 1993), externalizing problem behavior (Ladd & Burgess, 1999), the effects of deviant friends on delinquency and aggression (Keenan, Shaw, & Delliquadri, 1998; Kraatz-Keiley et al, 2000); and parent-child relationships (Sroufe, 1995). The basic tenets of transactional models have been cogently described by Sameroff (1995; Sameroff & MacKenzie, 2003). Within transactional systems, development is viewed as a dynamic process wherein characteristics of the child and characteristics of the environment undergo continual change through processes of mutual influence over time. The influence of any element of the

system is complex, and always bidirectional. The organism (child) in a transactional model is actively involved in attempts to organize and alter his or her environment. Changes in the environment as a result of a child's actions, on the other hand, subsequently function to produce changes in the child:

The child is in a perpetual state of active reorganization and cannot properly be regarded as maintaining inborn characteristics as static qualities. In this view, the constants in development are not some set of traits, but rather the processes by which these traits are maintained in the transactions between organism and environment. (Sameroff, 1975, p. 281)

From a transactional perspective, the development of psychopathology is neither a product of the child nor of the environment, but rather the result of child-environmental transactions that reinforce and sustain maladaptive patterns over time.

Figure 12.3 presents one possible way of representing the link between poor peer relationships in childhood and later disordered outcomes as a transactional developmental process. As in the earlier models, Figure 12.3 begins with the assumption that biogenetic and early experiential factors combine to contribute to a behavioral style that is maladaptive to forming friendships and interacting successfully in a peer group. The specific nature of this predisposing process is left unspecific and need not concern us here. It is also explicit in Figure 12.3 that these early experiences influence not only the child's initial maladaptive behavior toward peers (MB_1 in the model) but also the child's self-perceptions and social outlook, social motivation, and social attributions ($NSOC_1$ in the model). These self-other cognitive processes, in turn, also contribute to initial behavior toward peers. Importantly, as with the other two models, children's behavior toward peers is suggested to

Figure 12.3 A transactional model of the link between peer relationships problems and later disorder. Note: PPR = Problems in peer relationships; MB = Maladaptive behavior toward peers; NSOC = Negative self- and other-cognitions.

contribute (upward arrows) to initial difficulties forming friendships and peer rejection (PPR_1 in the model).

At this point the model departs notably from the other two models. Whereas the incidental and causal models attribute the development of disorder from this point to either processes in place in the child or stable processes set off by the environmental rejection, the transactional model in Figure 12.3 posits the operation of a dynamic pattern of continuous and reciprocal influence of children's behavior toward peers, problems in peer relationships, and children's negative self- and other cognitions. Thus, peer rejection negatively influences children's perceptions of self and others. This, in turn, influences them to behave in further maladaptive ways toward peers, which, in turn, negatively influences peers' attitudes and behavior toward them, and so on, in a spiraling fashion. One iteration of this spiraling cycle of cognition-behavior-rejection-cognition is represented by the pathway $NSOC_1 > MB_2 > PPR_3 > NSOC_4$, and this feature of the hypothesized model is discussed at greater length in the next section. The end point of this model indicates two, rather than one, sets of disordered outcomes. This duplication is deliberate, and intended to emphasize that most disorders have cognitive/affective as well as behavioral/symptom referents.

Several specific elements of the model require further mention. First, a path from each point of difficulty with peers to each successive point of difficulty with peers is articulated, and these paths are indicated with increasing thickness. This convention is adopted to recognize that, once in place, reputational and other factors contribute momentum to peer rejection, adding coherence to the process over time (LaFontana & Cillessen, 1999, 2002).

A similar convention is adapted from each point of behavior toward peers to each subsequent point of behavior toward peers (see Figure 12.3). This pattern is included as a means to represent the increasing canalization of behavior that results from the transactional operation of this cycle over time (Sameroff, 1987). Likewise the increasingly thick pathways from each point of self- and other-cognition to each subsequent point of self- and other-cognition is intended to recognize that these internal processes are somewhat self-perpetuating and have their own coherence over time, as we will discuss.

The elements in the model in Figure 12.3 have discrete subscripts at each hypothetical time point. This convention is adopted to highlight an important point about the transactional model: Even as they retain a certain lawful coherence over time, the elements of this model can be expected to change over time as a function of their participation in

the recursive cycles of influence (Sameroff, 1987). For example, initially active and aggressive children may, upon experience of peer rejection, appear sullen, withdrawn, and avoidant of peers later (Rubin, Burgess, & Coplan, 2002). As another example, children who behave unskillfully with peers may experience peer-group rejection initially, but not necessarily problems forming one or two same-sex friendships (Parker & Asher, 1993). Friendship problems may follow later, and, still later, problems relating to cross-sex others and romantic partners (Coie, 1990). Presumably, system-exogenous factors, such as how opportunities for cross-sex interaction are structured in the broader culture, partly dictate the specific nature of each element at a given time point. The broader point intended by the subscripts in Figure 12.3 is that the elements in the model should not be expected to stay constant—or even show homotypic similarity—over time (see Sroufe, 1995).

Transactional-like explanatory models have been increasingly invoked within the literature on children's peer relationships (Coie, 1990; Crick & Dodge, 1994). One illustration is the discussion by Rubin, Hastings, et al. (1998; Rubin & Burgess, 2002). Noting that a broad distinction is often drawn between internalizing and externalizing disordered outcomes, Rubin and colleagues describe the transactional pathways leading to these disparate eventual outcomes, and the complicity of peer rejection in these processes. Rubin et al. note that the distinction between externalizing and internalizing disordered outcomes parallels in certain respects the distinction between two types of at-risk infants: infants with difficult temperaments (negatively emotional, difficult to sooth, fussy, overactive) and inhibited infants with low thresholds for stimulation and arousal. Rubin et al. argue that this correspondence was not coincidental, and describe two hypothetical transactional pathways that might respectively link difficult temperament to later externalizing disorders and early inhibition to later internalizing disorder. Both pathways start with the assumption that when children with problematic temperaments are born into early risky caretaking environments (e.g., poverty, poor-parenting skills), the result is often a disruption in early parent-child attachment. In the instance of an infant with a difficult/fussy temperament, the result is often the creation of an avoidant-insecure attachment and a pattern of subsequent parenting that is authoritarian, hostile, and shows little concern for developing social competence. As a result, as preschoolers, these children behave more aggressively than other children, and hold less positive and trusting attitudes toward their peers. In this latter regard, we see the beginnings of social information processing deficits and biases. Because peers reject these chil-

dren, their cognitions and feelings toward peers become even more hostile, and their behavior toward peers becomes even more aggressive. Teachers label these children as problematic, and the parents of these children respond by becoming even more controlling and autocratic. Alternatively, some parents begin to view their children's problems as being dispositionally based; the result is a parental mindset that "there is little I can do to alter my child's aggressiveness." Parental hopelessness, permissiveness, or neglect may follow (Rubin & Burgess, 2002). Powerful reputation biases in the peer group are also set in motion, which make it even less likely for these children to be accepted by peers (LaFontana & Cillessen, 1999, 2002). Over time, this reciprocal cycle of peer rejection-negative cognitions and emotions-aggressive behavior-hostile parenting-peer rejection leads to the full exclusion and isolation of these children from the peer group. Indeed, by the end of elementary school, these initially aggressive children may even begin displaying higher-than-normal rates of social isolation as a reaction to the group exclusion. Rubin et al. suggest that the eventual prognosis for children who follow this pathway is the development of externalizing disorders (e.g., delinquency).

The pathway for children with initially inhibited temperaments is very different, however (Rubin, Burgess, & Coplan, 2002). When early caretaking circumstances exacerbate these children's difficulties, they will be prone to show difficulties characteristic of resistant-insecure attachment. They will be reluctant to explore their environment, will have less well-developed social and cognitive skills, and will show anxious, inhibited behavior with peers and high rates of nonsocial play as preschoolers. Even in early childhood, these children's social overtures to peers may be ignored or refused. The upshot of this early, *in vivo*, rejection is an exacerbation of social anxiety and withdrawal. Rubin et al. suggest that, for a variety of reasons, the parents of these children may react to their children's social difficulties by viewing them as vulnerable and in need of overprotection, thereby exacerbating their children's sense of insecurity (Rubin & Burgess, 2002). Rubin et al. suggest that, initially, during early childhood, researchers may not find a link with sociometric rejection; however, the transactional process between negative peer response and negative self-regard has already been set into place. Eventually, these socially wary children are viewed by peers as easy marks for teasing and victimization. As they move into elementary school, the children recognize the solidity of social failure and develop even more negative self-perceptions. Eventually, too, peers regard these children as socially awkward, atypical, and not worthy of social contact. As their rejection

by peers increases, Rubin et al. predict that these children react by becoming depressed and lonely, and eventually by showing internalizing disorders and difficulties relating to others as young adults. Importantly, Rubin and colleagues also note that the two trajectories involve children being involved in friendships that serve to exacerbate their difficulties. In the case of the first trajectory described above, the aggressive child finds himself or herself in the company of friends with whom deviancy training occurs. In the case of the latter trajectory, the anxious withdrawn child finds himself or herself in the company of friends with whom co-rumination occurs.

Transactional models such as the ones offered by Rubin and colleagues present formidable research challenges. Children's peer relationships, behavior, social-cognition, and adjustment are not expected to remain constant over time, and patterns of change over time must be used to predict subsequent changes and organism states. Progress in this area has been helped by the development of statistical techniques (e.g., structural equation modeling, growth curve analyses, survival analyses) for examining bidirectional and reciprocal influences in multivariate longitudinal data sets, but the number of investigations incorporating these techniques is still very limited.

In summary, investigators have offered simple main effects, interactional, and transactional explanations for why research has shown a link between early difficulties with peers and later maladjustment. Main effects explanations differ in the extent to which they view early difficulties with peers as involved in the etiology of the later disorders, with the incidental and causal being two extreme models. Such simple linear models seem insufficient explanations on the whole, however. Interaction models recognize that any attempt to specify how difficulties with peers affect later adjustment must consider aspects of the child, such as his or her preferred behavioral style and internal attributions and understandings. Interaction models, however, are still static characterizations. Recently, dynamic, transactional models have begun to influence how authors conceptualize and analyze the link between early peer difficulties and later adjustment. These transactional models offer many advantages over other explanations because they recognize that the child and the peer group form a dynamic, interacting system that changes over time. A significant element of this system includes the mechanisms of reciprocal influence among the child's cognitions of the self and others, the child's behavior toward peers, and the peer group's collective appraisal of and behavior toward the child. This element is the focus of the next section.

PROCESSES OF RECIPROCAL BEHAVIOR AND SOCIAL COGNITION IN PEER GROUP ADJUSTMENT

In the preceding discussion of transactional models, we described a hypothetical spiraling cycle of influence, wherein children and their peers form impressions and perceptions of one another that guide their behavioral responses toward each other and determine the nature of their relationships. The components of this process included the child's cognitions about him- or herself, the child's characteristic behavior toward peers, the influence of the child's behavior on the peer group's collective appraisal and acceptance of the child, and the resulting influence of these attitudes on the peer group's collective behavior toward the child. Although this reciprocal process was presented abstractly earlier, in fact a great deal is already known about many of these variables and pathways of influence. Indeed, theory and research on the mechanisms that govern adult social interaction has a long history (e.g., Kelly, 1955) and continues to flourish (e.g., Fletcher & Fincham, 1991), while several models of the mechanisms that govern the social interaction of children have also been presented (e.g., Crick & Dodge, 1994; Lemerise & Arsenio, 2000; Rubin, Hastings, et al., 1998). Also, as we have reviewed, the study of the behavioral correlates of difficulties with peers is one of the oldest traditions within the literature on children's peer relationships. Interestingly, it was the empirical evidence indicating that children who experience peer difficulties are at risk for both concurrent and later maladjustment that served as the major impetus for what is now a substantial body of research focusing on the social-cognitive and behavioral processes underlying peer difficulties.

Our purpose in this section is to flesh out this emerging general model of how children's cognitions, emotions, and behavior affect the establishment of negative reputations among peers and peer group rejection by reviewing the existing research bearing on its key components and pathways. Before beginning, it merits noting that in several respects the research in this area has followed a developmental psychopathological perspective. First, there is an implicit understanding that the study of social maladjustment is linked with the study of normal social development. One of the major tenets of developmental psychopathology is that our understanding of risk and pathology can be enhanced by knowledge about normal development. Likewise, our understanding of normal development is expanded by knowledge about deviations in development (Cicchetti, 2002). Much of the research on the social-cognitive and behavioral correlates of peer difficulties has involved identi-

fying children who are experiencing social difficulties (e.g., children who are rejected, withdrawn, or friendless), assessing their social-cognition or behavioral orientations, and then comparing their orientations to those of children who are functioning successfully within their peer groups. As a consequence, a great deal has been learned about the social-cognitive and behavioral processes underlying both successful and unsuccessful peer relationships.

Second, there is the recognition by researchers in this area that there are likely to be different pathways by which children come to experience peer difficulties. The view that the same developmental outcome may be achieved through different avenues is a position advocated by developmental psychopathologists. For example, whereas some children can become rejected because they behave aggressively and disruptively, others may become rejected because they withdraw from peers and engage in developmentally inappropriate play (Rubin, Hastings, et al., 1998).

Finally, there is the realization, as there is in developmental psychopathology, that there are multiple mechanisms and processes involved in determining a particular maladaptive outcome. Consequently, a variety of cognitive, emotional, and behavioral mechanisms and processes have been examined, including the social-cognitive and behavioral characteristics of children who are experiencing social difficulties, as well as the social-cognitive and behavioral responses of the peers with whom the child interacts.

Although the general outline of the process we wish to describe was embedded in Figure 12.3, this process is shown in a different and clearer form in Figure 12.4. The cycle shown in Figure 12.4 is one in which the processing of social cues, the regulation of emotion and emotion processing, and the social behavior of both the target child and the members of the peer group contribute to difficulties in peer relationships or peer rejection. Figure 12.4 is a representation of the conclusions of recent research and theorizing in this area, including models offered by Coie (1990), Crick and Dodge (1994), Deater-Deckard (2001), Howes (1988), Lemerise and Arsenio (2000), and Rubin and Rose-Krasnor (1992), among others. The model in Figure 12.4 is guided by several assumptions. First, it is assumed that each individual brings into the interactive context broad representations of him- or herself and his or her relationships. These representations guide children's expectations for interaction and direct them to pursue some social goals but not others. They also influence how children interpret the behavioral cues of their interactive partners and how children evaluate alternative response options.

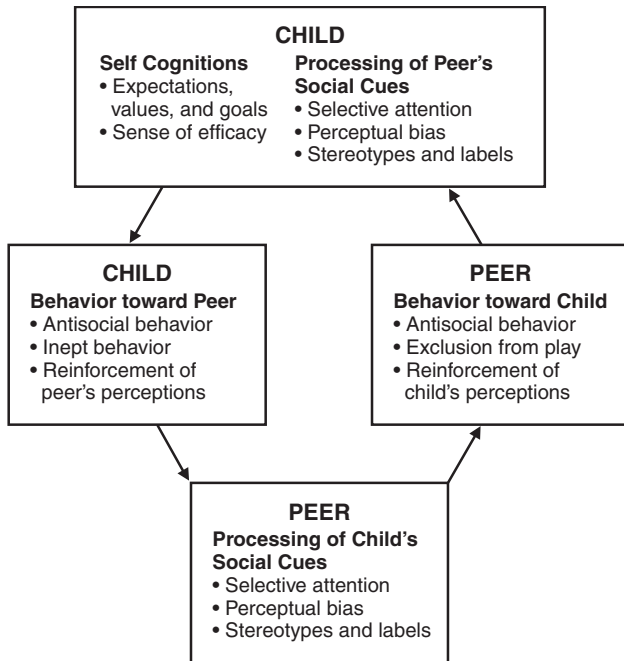

Figure 12.4 Processes of reciprocal influence in peer transactions involving children with poor adjustment with peers. Adapted from “Peers’ Contribution to Children’s Social Maladjustment: Description and Intervention” (pp. 341–370), by J. M. Price and K. A. Dodge, 1989, in *Peer Relations in Child Development*, T. J. Berndt & G. W. Ladd (Eds.), New York: Wiley.

Second, the model assumes that from the earliest periods of interaction, participants form specific expectations and representations of their particular partner. These representations may include the behavioral characteristics of the other, as well as emotional reactions that were experienced at the time the representation was formed. These person representations are integrated into previously existing knowledge structures, and in concert with these structures, guide each participant’s behavioral responses. The valence of these person representations is extremely important. If primarily positive, then future interaction with the partner is welcomed and pursued. If, however, the valence of the behavioral and affective features of the representation of the other are primarily negative, then further interaction with that particular individual might be avoided. This process of forming person perceptions is considered to be dynamic rather than static. As long as two individuals are continuing to have contact with one another, there is the potential for the modification of existing representations and perceptions.

Finally, and consequently, the model assumes that the social outcomes of interactions (e.g., the degree to which the individuals like one another or whether they become friends) follow from the person perceptions that are formed

during the course of interaction. We turn next to some of the specific components of the model in Figure 12.4.

The Child’s Self and Social Cognitions

The first component of interaction consists of the child’s self, social cognitions, and emotions. When a child interacts with a peer, he or she applies a set of knowledge structures about the self, about relationships in general, and, if there has been prior experience with a particular peer, specific knowledge and memories about that peer. He or she also applies a set of specific social goals and expectations for the interaction. These goals and expectations also reflect beliefs about his or her personal and emotional efficacy in relationships in general and in the specific relationship at hand. It is hypothesized that during social interaction, these knowledge structures, emotions, and expectancies influence how the individual processes the social information available (Crick & Dodge, 1994; Deater-Deckard, 2001; Lemerise & Arsenio, 2000; Rubin & Rose-Krasnor, 1992; Saarni, 1999). In turn, the manner in which this information is processed serves to guide the child’s behavior during interaction with the peer. Thus, positive views and expectations of self and relationships, along with accurate processing of information and positive emotions, should be conducive to the formation of positive and supportive relationships with peers. Conversely, negative views and expectations of self and others, along with processing biases and deficits and negative emotions, should lead to social difficulties with peers.

Self Cognitions

Children’s self regard and self appraisals of their social competencies should have an important bearing on the ways they initiate and maintain social exchanges with peers (X. Chen et al., 2004; Sandstrom, Cillessen, & Eisenhower, 2003; Sandstrom & Coie, 1999). Positive self appraisals are likely to prove advantageous for the initiation of social interaction; negative self evaluations may prove disadvantageous in promoting social exchange. The dialectic between self-regard and social interaction tendencies is an area that requires serious inquiry. At present, what is known is that popular children tend to view themselves as more socially competent than their less popular age-mates, with the association between acceptance and self appraisal increasing with age (Bukowski & Hoza, 1989; Ladd & Price, 1986; Sandstrom et al., 2003; Sandstrom & Coie, 1999). Peer rejection, on the other hand, is associated with negative thoughts and feelings about the self. Unpopular or

rejected children are more likely than their popular counterparts to express a less positive self-concept in the social and they are also more likely to perceive social situations as difficult (Sandstrom et al., 2003; Sandstrom & Coie, 1999). Unpopular children are more likely to report greater anxiety in social situations (Flanagan, 2005; Hymel & Franke, 1985; La Greca et al., 1988).

Although these findings suggest the general conclusion that children already experiencing difficulties with peers approach social situations feeling poorly about their social relationships and social skills, it is important to note that not all children with poor peer relationships approach social situations in this negatively disposed way. Studies of sociometrically rejected children indicate that one subset of these children, those who behave aggressively, do not report thinking poorly about their social relationships with peers (Zakriski & Coie, 1996). Rejected children who are anxious and socially reticent do, however (Hymel, Bowker, & Woody, 1993). These findings are in keeping with the results of studies concerning extremely withdrawn and extremely aggressive children; it is only the former group that reports having difficulty with their social skills and peer relationships (Boivin & Hymel, 1997; Rubin, Chen, & Hymel, 1993).

Furthermore, children who are victimized by their peers, particularly those children who self-report themselves as victimized, are more likely than their nonvictimized peers to blame themselves for their social difficulties, to report anxiety, and to indicate low feelings of overall self-worth (Graham & Juvonen, 1998).

Social Cognitions

In addition to perspectives on the self, cognitions about others and relationships are expected to be associated with, and predictive of, social difficulties with peers. Although little is known about the role of latent knowledge structures in children's social adjustment, considerable information exists on the relation between social information processing patterns of children and social outcomes (e.g., Brendgen, Bowen, Rondeau, & Vitaro, 1999; Burks, Laird, Dodge, Pettit, & Bates, 1999; Dodge, Lochman, Harnish, Bates, & Pettit, 1997; Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002; Rose & Asher, 2004). To date, several theoretical models of the link between social information processing and behavior have been formulated. For example, in the social information processing model described by Rubin and Krasnor (1986), when children face an interpersonal dilemma (e.g., making new friends or acquiring an object from someone else), their thinking follows a particular

sequence. First, children may select a social goal. This entails the establishment of a representation of the desired end state of the problem-solving process. Second, they examine the task environment; this involves reading and interpreting all the relevant social cues. For example, boys and girls are likely to produce different solutions when faced with a social dilemma involving same-sex as opposed to opposite-sex peers (Rubin & Krasnor, 1983). As well, the social status, familiarity, and age of the participants in the task environment are likely to influence the child's goal and strategy selection (Krasnor & Rubin, 1983). Third, they access and select strategies; this process involves generating possible plans of action for achieving the perceived social goal, and choosing the most appropriate one for the specific situation (Burgess et al., 2005; Rabiner & Gordon, 1992; Rose & Asher, 2004). Fourth, they implement the chosen strategy. Finally, it is proposed that children evaluate the outcome of the strategy; this involves assessing the situation to determine the relative success of the chosen course of action in achieving the social goal. If the initial strategy is unsuccessful, the child may repeat it or she or he may select and enact a new strategy, or abandon the situation entirely.

In an initial attempt to understand the production of aggression in children, Dodge (1986) proposed a similar model of social information processing. This model was later revised by Crick and Dodge (1994) and then by Lemerise and Arsenio (2001), and has been applied to many different groups of children, including different types of aggressive children and nonaggressive children (Crick & Dodge, 1996), children of different sociometric status (Crick & Werner, 1998), and children experiencing depression and anxiety (Bell-Dolan, Foster, & Christopher, 1995; Garber, Keiley, & Martin, 2002; Quiggle, Garber, Panak, & Dodge, 1992). The Crick and Dodge (1994) model consists of six stages, namely, (1) the encoding of social cues; (2) the interpretation of encoded cues; (3) the clarification of social goals; (4) the accessing and generation of potential responses; (5) the evaluation and selection of responses; and (6) the enactment of the chosen response. An additional component of this model is a "database" comprised of biologically determined capabilities and cognitive structures acquired from past experiences, such as social schemas, scripts, and knowledge, which are thought to directly influence each information processing step (Crick & Dodge, 1994).

Children who have difficulties in their peer relationships demonstrate characteristic deficits or qualitative differences in thinking at various steps of these models. Several types of deficits or differences have been identified:

- Children with problems in peer relationships have difficulty discriminating a peer's social intentions. Dodge, Murphy, and Buchsbaum (1984), for example, found that popular children are better than other children at discriminating a peer's intentions, whereas rejected children are significantly worse. The importance of attending to relevant social cues is that these cues are then used to interpret another's intentions.
- Rejected children, particularly rejected children who are aggressive, are more likely than their more popular counterparts to assume malevolent intent when they are faced with negative circumstances, especially when the social cues are ambiguous (e.g., Dodge et al., 2003; see Orobio de Castro et al., 2002, for a recent review). Moreover, socially accepted (popular) children tend to attribute social successes to internal causes and expect success to continue in the future (Sobol & Earn, 1985). They also view social outcomes as more controllable than do socially unaccepted children. Alternately, children experiencing social difficulties tend to perceive their social successes as unstable and externally caused and to perceive their social failures as stable and internally caused (e.g., Dill, Vernberg, & Fonagy, 2004; Rubin & Krasnor, 1986; Wichmann, Coplan, & Daniels, 2004).
- Accepted and unaccepted children differ in their social problem-solving skills. Children who are well liked are likely to generate competent and effective solutions to interpersonal dilemmas, whereas disliked children are likely to generate incompetent or aggressive solutions (e.g., Asarnow & Callan, 1985; Ladd & Oden, 1979; Pakaslahti, Karjalainen, & Keltikangas-Jaervinen, 2002; Rubin & Daniels-Beirness, 1983), especially if they view the other's intentions as hostile (Dodge, 1980).
- Socially accepted children differ from disliked children in the manner they evaluate the probable outcomes for their behavior. In general, well-liked children are more accurate in their evaluations of the outcomes of their behavior. Disliked children, however, expect that positive outcomes will accrue if they act aggressively and that less-positive outcomes will result from nonaggressive solutions (Perry & Rasmussen, 1986). Also, compared to nonaggressive children, aggressive children are more likely to believe that an aggressive response is appropriate, and are more likely to expect positive outcomes from an aggressive response (Guerra, Huesmann, & Splinder, 2003; Huesmann & Guerra, 1997).

Complementing this research on the link between social cognition and peer difficulties is research on the relation

between social information-processing and behavior. Results from research with both extreme and normal samples indicate that the manner in which children process information is related to their actual behavior, particularly when aggregated assessments of processing are conducted (e.g., Erdley & Asher, 1998; Orobio de Castro et al., 2002; Orobio de Castro, Bosch, Veerman, & Koops, 2003). Moreover, a recent study found that social information-processing mediated the association between early peer rejection and later aggressive behavior (Dodge et al., 2003). Thus, there is empirical evidence that children's social cognitions serve to guide their behavioral orientations and responses with peers.

Finally, there are experimental data supporting the link between a child's social cognitions and his social behavior and adjustment. In a novel experiment by Rabiner and Coie (1989), rejected participants were given the assignment of entering a room to initiate play with a group of peers with whom they were unacquainted. Half the boys were told that the peers liked them and wanted them to play with them. The other half was not given any kind of expectation. Consistent with evidence presented in this section, relative to the boys not given an expectation, rejected boys who expected to be liked came to be liked more by the peers. Presumably, a child's expectations of being liked led him to behave in ways that led the peers to like him.

Emotions

Recent research has demonstrated that children's emotions are associated with their peer experiences. Such research stems from the work of Saarni (1998, 1999) on emotional competence, and from a recent reformulation of Crick and Dodge's (1994) model by Lemerise and Arsenio (2000) that places emphasis on emotion processes and cognitions. Specifically, Lemerise and Arsenio argue that emotional processes should be considered at each stage of Crick and Dodge's social information processing model. For example, a child's negative emotionality or reactivity and emotion regulatory skills, in addition to the affect component of a child's representations of past experiences, should be included in the "database" that each child brings to a social situation. Also, the ways in which children encode and interpret cues may be affected by a child's mood, emotions, and arousal, and may be influenced by other peers' own affective states and emotions. For example, an offending peer with a visibly happy face may dissuade a child from assigning blame. Similarly, Lemerise and Arsenio posit that other peers' affective states and cues may influence the type (positive or negative) of goals that children

choose. Furthermore, the emotional ties that children have with others might influence the ways in which children generate, evaluate, and choose a response in a social situation. Presumably, if a child has a close, intimate relationship with another, the child will process the social information positively, and choose responses that will be likely to promote maintenance of the relationship (e.g., Burgess et al., 2005).

There is some evidence that children's expressions of emotions are related to sociometric status. Compared to average-status children, Hubbard (2001) found that rejected children expressed more anger and nonverbal unhappiness. Moreover, children's emotional competence (a composite of emotional expressiveness, emotion regulation, and emotion knowledge) in 3- and 4-year-olds is concurrently and predictively associated with social competence (Denham et al., 2003). Importantly, an intervention study conducted with aggressive boys revealed that emotion regulation may influence social-information processing (Orobio de Castro et al., 2003). In this study, when aggressive boys were asked to monitor and regulate their emotions, and also to consider the emotions of the peer instigator, the children generated behavioral responses that were less aggressive in nature. The study of the influence of emotion processes on social information-processing represents an exciting new research direction that will further our understanding of social information processing, and may in turn, improve our attempts to intervene with children who experience difficulties with peers.

Child's Behavior toward Peers

The second component of the reciprocal influence model is the behavior the individual displays toward other children. Children's behavior toward other children is presumed to be driven by their self- and social cognitions. In turn, children's behavior is expected to influence the perceptions that other children develop of the child (see Figure 12.4).

A considerable body of research suggests that, although children are sometimes rejected by peers for nonbehavioral reasons such as physical stigmata, behavior plays a substantial, if not overriding, role. Many studies have documented behavioral differences between socially successful children and children experiencing difficulties in their relationships with peers (see Bierman, 2004). Much of this work is based on cross-sectional research designs utilizing existing peer groups. Such studies are open to the alternative interpretation that the behavioral differences are the result of rather than responsible for children's difficulties

with peers. Children's behavior is undoubtedly affected by being rejected by peers, however, enough research now exists to safely conclude that how children behave shapes their reception by the peer group in the first place. A set of classic longitudinal studies and studies utilizing artificial play groups, for example, show that behavioral assessments made before or during the earliest stages of acquaintance-predict children's subsequent social acceptance (e.g., Coie & Kupersmidt, 1983; Dodge, 1983; Putallaz, 1983). More importantly, intervention studies designed to reduce children's negative behaviors or increase their repertoire of social skills have shown increases in acceptance by peers as a result of behavioral changes (see Bierman, 2004, for a recent review).

Which behaviors matter? Most research has focused on the behavioral basis of peer acceptance or rejection. Research on the behavioral correlates of sociometric standing is a several-decades-old tradition, and many lawful associations between specific behaviors and rejection by the peer group have been documented (see Rubin, Bukowski, et al., 1998, for a review). One broad class of behavior that has proven to be especially significant is aggressive behavior. Aggressive behavior has been found to correlate with rejection by peers regardless of whether peer evaluations, teacher ratings, or direct observations (Crick, Casas, & Mosher, 1997; Haselager, Cillessen, Van Lieshout, Riksen-Walraven, & Hartup, 2002; McNeille-Choque, Hart, Robinson, Nelson, & Olsen, 1996) are used to assess children's social behavior. Furthermore, both physical and relational forms of aggression have been linked with peer rejection (Crick & Grotpeter, 1995; Underwood, 2003).

However, recent research indicates that rejection and victimization by peers may hinge, in part, on the behaviors concomitant with aggression, rather than aggression per se. Aggressive behaviors appear to place children at highest risk for peer rejection when they occur along with a broad pattern of emotionally reactive, disruptive, and unskilled behavior (Bierman, 2004). For instance, "ineffectual" and "effectual" aggressors have been distinguished on the basis of their behavior in conflict situations and on their peer experiences (Perry, Perry, & Kennedy, 1992). Ineffectual aggressors prolong and escalate conflicts, exhibit exaggerated displays of negative emotion, and eventually "lose" in conflict situations. These children are at high risk for peer rejection and victimization. In contrast, effectual aggressors behave aggressively in the service of instrumental goals and to establish dominance, and they do not prolong conflicts or exhibit heightened emotion. These children encounter little resistance from peers and are rarely victim-

ized by peers (Perry et al., 1992). According to the results of a 2-year longitudinal study, aggressive-rejected children are more likely to experience stable elevations in aggressive behavior and peer rejection than aggressive-nonrejected and nonaggressive-rejected children (Bierman & Wargo, 1995). Importantly, research indicates that aggression may not lead to rejection if it is balanced by a set of positive qualities (e.g., social skill) that facilitate links with other children (Farmer et al., 2003).

In addition, extremely withdrawn children have been found to be more lonely and disliked and victimized by peers than are their more sociable age-mates, especially during the mid-to-late years of childhood (see Rubin, Burgess, & Coplan, 2002, for a review).

On the other hand, observational studies also suggest that children who engage in high rates of positive social behavior (e.g., conversation, smiling, prosocial sharing, and helping), who make efforts to initiate contact with others, who join ongoing play in a fluid and natural way, who cooperate, and who respect peer norms, are likely to receive more positive behavioral responses from peers and to have higher peer sociometric rating and nomination scores than other children (see Coie, 1990; Eisenberg & Fabes, 1998; Newcomb, Bukowski, & Pattee, 1993). Similarly, children who are described by their peers as helpful, supportive, cooperative, friendly, nice, calm, understanding, good at games, and good leaders are more likely to receive high sociometric ratings and many positive and few negative sociometric nominations (see Rubin, 2002). Thus, the presence of positive social skills as well as the absence of aggressive or extremely withdrawn behavior seems critical to acceptance by peers (Bierman, 2004). Bierman (2004) identified seven social skills domains that are frequently selected for social skills training on the basis of their empirical association with peer acceptance. These skill domains include social participation, emotional understanding, prosocial behavior, self-control, communication skills, fair-play skills, and social problem-solving skills.

Recent research has also emphasized the affective dimension of socially competent behavior. Halberstadt, Denham, and Dunsmore (2001) identified sending affective messages, receiving affective messages, and experiencing affect as three integrated components of affective social competence. Sending affective messages involves awareness of the need to send such a message, identification of which message to send, sending a message consistent with the demands of the situation, and managing the delivery of the affective message. Children who are more positively expressive and more adept at sending affective messages

are better liked by peers than children who are negatively expressive (Halberstadt et al., 2001). The emergence of the affective social competence model is consistent with recent conceptualizations of social competence. Eliciting positive peer responses requires not only a repertoire of appropriate behaviors, but also emotion regulation and social-cognitive skills which foster behavior that is appropriate and responsive to social and situational demands (Bierman, 2004; Sroufe, 1996).

Although the correlates of acceptance and rejection appear to be similar across age groups, Coie (1990) points out a few developmental differences that have been identified. For example, as children enter into elementary school, both athletic and academic competence becomes increasingly important determinants of social adjustment in the peer group. Children who display competence in either one or both of these domains are better liked by their peers who are less competent. In addition, with age, disruptiveness in the classroom and social withdrawal become increasingly important contributors to social rejection. Recently, Cillessen and Mayeux (2004) found that relational aggression was increasingly predictive of perceived popularity but decreasingly predictive of peer liking (i.e., sociometric popularity) from middle childhood to early adolescence; physical aggression was increasingly less disliked by peers and decreasingly predictive of perceived popularity. And, although much less is known about this issue, it appears that the behavioral correlates of peer acceptance and rejection also differ somewhat for children of different genders and from different socioeconomic circumstances (see Bierman, 2004).

Specific behaviors have also been shown to be related to the development and maintenance of friendships, although much less is known about this process (Berndt, 2002, 2004). It has been demonstrated that among children who are "hitting it off," communication becomes increasingly connected, conflicts that arise are successfully resolved, and play activities are coordinated (Gottman, 1983). As the relationship progresses, communication clarity and self-disclosure become increasingly important. Once friendships are established, cooperation and reciprocity become key elements of successful relationships (see Hartup & Stevens, 1997). Thus, the child's ability to engage in joint communication and cooperative activities with a peer as well as successfully resolve conflicts with that peer, appear to be important behavioral skills for friendships (Laursen, 1993; Laursen, Finkelstein, & Betts, 2001; Parker & Seal, 1996). On the negative side, children's behavioral orientations also have been found to contribute to the development

of less desirable relationships, such as antagonistic, conflicted relationships and bully/victim relationships (Hartup & Abecassis, 2002). For example, Dodge, Price, Coie, and Christopoulos (1990) identified high-conflict, low-conflict, asymmetric (bully/victim relationships), and low-interaction dyads that developed in small play groups. Their results indicated that the rate of aggressing toward a peer was positively correlated with the rate of being the object of the peer's aggression. These aggressive exchanges contributed to the development of stable high-conflict relationships. Once developed, participants of high-conflict dyads were more aggressive toward one another and engaged in less prosocial behavior than other dyads. Not surprisingly, participants of these relationships came to dislike each other. Recent research indicates that dyadic relationship factors contribute more variance to boys' reactive aggression and hostile attributions within dyads than do actor or partner factors; furthermore, social cognitions that predict reactive aggression within dyads seem to be best explained at the dyadic level (Coie et al., 1999; Hubbard, Dodge, Cillessen, Coie, & Schwartz, 2001). That is, although general social-cognitive tendencies impact dyadic reactive aggression, social-cognitive biases that contribute to reactive aggression seem to be somewhat specific to dyadic relationships (Hubbard et al., 2001).

Obviously, a vast array of positive and negative behaviors has been linked to the development of successful and unsuccessful relationships with peers. Indeed, any attempt to catalogue the hundreds of specific behaviors that have been studied in relation to various social outcomes quickly becomes unwieldy. In an effort to impose some conceptual organization on the existing litany of behavioral correlates and to identify areas of relative neglect, Asher and Williams (1987) suggested a useful framework for considering the kinds of behaviors that should relate to adjustment with peers.

According to Asher and Williams (1987), when considering the kinds of behavior that are likely to contribute to adjustment with peers it is helpful to consider how children come to a conclusion about whether they like or dislike another child. These authors suggest that children pose a set of six metaphoric questions to themselves. The core issues for children are: (1) whether they find the partner entertaining, (2) whether they feel that they can trust the partner, (3) whether they find that the partner influences them in ways that they find acceptable, (4) whether they find that the partner facilitates rather than undermines their personal goals, (5) whether the partner makes them feel good about themselves, and (6) whether they can conclude that the partner shares their fundamental values and priorities.

Asher and Williams (1987) suggest that by considering these core issues for children, one can better understand which behaviors should and should not be expected to be related to success with peers, and why some behaviors are more robust correlates of social success than others. Behaviors that simultaneously address several core issues for children are expected to be stronger correlates of social success than behaviors that address only one concern. This argument, for example, would explain why aggression is such a strong correlate of adjustment with peers: Children who are aggressive are not fun to be around (issue A), humiliate others (issue E), are unpredictable (issue B), disrupt activities (issue D), and generate resentment (issue C). A further important element of Asher and Williams' framework is that it is the configuration of children's behavioral assets and liabilities that is most important, not the presence or absence of any single specific behavioral tendency. Thus, aggressive children who nonetheless possess skills for behaving in ways that leave others feeling good about themselves or to find them entertaining, trustworthy, persuasive, and so on, are not expected to run the same risk of peer rejection as aggressive children without these additional social skills (see Bierman, 2004). The significance of particular negative behaviors such as aggressiveness or social withdrawal, therefore, depends partly on whether child also possesses offsetting social skills. In the following section, peers' perception of the child will be explored in greater detail.

Peers' Social Cognitions

One of the basic propositions of the social interaction model is that from their initial encounter, social partners are forming representations and perceptions of one another. These cognitive processes are depicted in the third component of Figure 12.4. As is supported by the research reviewed in the previous section, children's representations and perceptions of one another are, at least in part, based on the behaviors they direct to one another. There is also evidence that children's memories and perceptions of one another are influenced by their own behavioral reputation, level of peer status, age, and liking for the peer target; situational factors (e.g., the levels of aggression within the peer group; and the peer target's gender, age, and socio-metric status; Bierman, 2004; LaFontana & Cillessen, 1999, 2002).

Once children's perceptions of one another are formed, they appear to remain moderately stable over time (LaFontana & Cillessen, 1999, 2002). Thus, the impressions that are formed of a child within a particular peer group

are likely to be maintained over time. One explanation for the stability of person perceptions is that the structure of social cognitive processes appears to be favorable to the maintenance of the perceptions and impressions.

To begin, there is evidence that individuals selectively attend to certain types of behavior displayed by their interactive partner, depending on their attitudes and perceptions of that particular partner. Relevant information (i.e., information that is either consistent or inconsistent with the knowledge structure) is attended to whereas irrelevant or neutral information is not. Thus, when interacting with a child, the types of behavioral displays that are likely to be attended to will be based, at least in part, on the peer's perceptions of the child. If the child is perceived to be friendly or is liked by peers, then prosocial or cooperative behavior may be a part of the peers' scheme for the child. These behaviors would be attended to. If, however, the child was perceived as aggressive or was disliked, then antisocial behaviors would be a part of the peers' schema, and as a consequence, future aggression would be likely to be attended to. In both scenarios, peers' original perceptions and representations of the child would be reinforced.

Attribution processes also appear to be oriented toward the maintenance of previously developed person perceptions. According to social information processing theorists, attributions primarily occur at an unconscious, automatic level, unless the individual behaves in an unexpected manner, is highly negative, or there is some kind of affective arousal (the peer threatens the child). These particular conditions are hypothesized to trigger explicit, conscious processing (Dodge, 1986; Rubin & Rose-Krasnor, 1992), which may lead to a modification of the original representations of the child. Thus, when interacting with a child, a peer will consciously engage in attributions only when the child is particularly negative or acts in a manner inconsistent with the peer's perceptions or schema for the child.

The automation of attributions also appears to be guided by a number of biases. Research with adults indicates that when interpreting another's behavior, individuals tend to show a bias toward confirming rather than disconfirming their existing perceptions (Fiske, 2004). Thus, unless the behaviors displayed by the partner are so highly inconsistent with developed person perceptions as to lead to conscious processing, behavioral displays are interpreted as being consistent with person perceptions (Hymel, 1986). For example, children will be more likely to attribute hostile intentions to a child they know as aggressive than to a child known to be nonaggressive. Likewise, Burgess et al. (2005) recently reported that children are *less* likely to attribute hostile intentions to a best friend than to a stranger.

Finally, Hymel (1986) found that children's explanations of a child's behavior varied as a function of both affect toward the child and the valence of the child's behavior. For liked children, positive behaviors were attributed to stable causes (e.g., traits), whereas for disliked children, negative behaviors were attributed to stable causes.

Peers' Behavior toward Child

The final component in the model of children's social interactions as depicted in Figure 12.4, is the behavioral responses directed toward the child by the peer group. Once formed, children's reputations guide other children's behavior toward them (Zeller, Vannatta, Schafer, & Noll, 2003). For example, in a classic and persuasive study, Dodge (1980) presented children with hypothetical stories about classmates with differing reputations for aggressiveness with peers. Dodge found that children were more likely to retaliate aggressively when an act was performed by a classmate with a reputation for aggressiveness, than when the same act was performed by a nonaggressive classmate.

The reputation frames that guide children's behavior toward a specific child are important, as they may entice the child who is the object of a negative reputation to behave, in turn, in ways that affirm this reputation. Indeed, research with adults indicates that when an individual expects another individual to behave in a certain way (e.g., to be friendly or unfriendly; hostile or nonhostile), his or her partner's behavior may indeed fall in line with these expectations. Thus, when an individual is led to expect unfriendly behavior from a partner, his or her behavior may indeed inspire unfriendly behavior from partners. In addition, research with adults (e.g., Fiske, 2004) indicates that individuals sometimes make inferences about other people's characteristics by referencing his or her own behavior. In a similar fashion, to the extent that children reference his or her own behavior to make inferences about another child, and their own behavior is motivated by reputation, those reputations may be strengthened. In this way, the spiraling cycle of child's cognition—child's behavior—peers' cognitions—peers' behavior is reinforced.

Illustrating the Developmental Psychopathological Approach to Peer Adjustment: The Example of Social Anxiety with Peers

In this section, we illustrate how principles of developmental psychopathology may be applied to illuminate the etiology,

nature, course, and treatment of child social anxiety. Interest and research pertaining to social anxiety in children has flourished in recent years, in part, due to documentation that social anxiety places individuals at risk for problematic developmental outcomes and, in part, due to broader increased interest in the interface between emotion, cognition, and behavior. Evidence suggests, for instance, that social anxiety is linked concurrently with depressed mood, other anxiety disorders, and school maladjustment (Beidel & Turner, 1998; Morris, 2001; see Crozier & Alden, 2001, for recent reviews). In addition, social anxiety places children and adolescents at risk for social and psychological maladjustment in adulthood, including the development of other anxiety disorders, major depression, substance use disorders, and impaired occupational functioning (Beidel & Turner, 1998).

Social anxiety may be conceptualized in several alternative ways, but it is especially fruitful to view social anxiety as a form of peer maladjustment. Indeed, a growing body of research provides evidence for an association between child social anxiety and peer maladjustment. For example, cross-sectional studies with both normative and clinical child populations indicate that social anxiety is linked with self-reports of limited and low quality friendships and loneliness (Beidel & Turner, 1998; Flanagan, 2005; LaGreca & Lopez, 1998; Vernberg et al., 1992). Social anxiety has also been linked with sociometric ratings of low peer group acceptance and victimization by peers (Flanagan, 2005; Inderbitzen et al., 1997; La Greca & Stone, 1993). In addition, in retrospective accounts, socially anxious adults report fewer friends during childhood than nonanxious adults (Rapee & Heimberg, 1997) and they identify negative social experiences as contributing to the onset of social anxiety (Stemberger et al., 1995).

These associations are significant in their own right but they become of further interest as we consider the ways in which they might illustrate important principles of developmental psychopathology. For example, developmental models suggest that social anxiety emerges, in part, as a result of reciprocal transactions between individual characteristics and the social context. Rubin and colleagues have advanced a developmental model in which behavioral inhibition and social reticence in early childhood increase the risk for social skill deficits and social anxiety (e.g., Rubin, Burgess, Kennedy, et al., 2003). Rubin et al. contend that children with temperamental vulnerabilities, such as behavioral inhibition, initially experience psychological and physiological discomfort in social situations, which leads them to avoid social interaction (Rubin, Burgess, & Hast-

ings, 2002). Avoiding social interaction during early childhood limits important socialization opportunities, which in turn, impedes the normative development of social cognition and social skills in these children. These children's social skill deficits then elicit negative peer reactions which, in turn, perpetuate further social withdrawal and intensify social anxiety (e.g., Nelson, Rubin, & Fox, *in press*). Further, inhibited and reticent behavior may mark socially anxious children as easy targets of overt rejection and victimization by peers attempting to establish social power and dominance (Hodges, Malone, & Perry, 1997). It is easy to imagine how peer victimization would exacerbate the social avoidance and anxious affect that may have invited victimization in the first place. This apparent reciprocal cycle of characterologic vulnerability, negative peer experiences, and problematic behavior is an excellent example of an important principle of developmental psychopathology, namely, that maladjustment is an outcome of reciprocal transactions between individuals and their social-ecological contexts (Cicchetti, 2002; Sameroff, 1995).

Likewise, an additional principle of developmental psychopathology is that normal and abnormal developmental processes are mutually informative. Rates of social anxiety increase markedly during the late childhood and early adolescent years (Beidel & Turner, 1998), with an average age of onset around 12 years (D. D. Weiss & Last, 2001). What accounts for this normative increase in this form of problematic behavior? It is possible that diagnostic or other more prosaic factors account for this developmental trend, but we find it interesting to speculate that the patterns of prevalence of social anxiety may be linked to exaggerations or distortions in normative developmental processes. Consider first that important developmental shifts take place in social cognition during the same developmental period that many children begin encountering significant difficulties with social anxiety for the first time. It is during this same period of time, for example, that children increasingly evaluate themselves in comparison to other children rather than to absolute standards (Parker et al., 1995). Likewise, developments in abstract thinking and perspective taking at this age heighten children's awareness of peer evaluation and alter their appreciation for the content and valence of peer perceptions (Crozier & Burnham, 1990). These social cognitive developments are important developmental mileposts that typically serve children well in the long run, even if they contribute to the reasonable self-consciousness that most children show at this age. But, in view of evidence that distorted and negatively biased self views are implicated in the social anxiety, it is tempting to conclude that these same normative changes also contribute to a rising

tide of more problematic social anxiety when they occur within vulnerable individuals.

Along with being an era of normative changes in social and self-cognition, the period for heightened identification of social anxiety is also a period of heightened pressure for social participation with peers. As discussed earlier, it is during the period in which social anxiety becomes prevalent that children begin spending substantial amounts of time away from their families with peers. Most children initiate this re-orientation themselves and desire and welcome it. But it also is anticipated and encouraged by parents, teachers, and others, and thus does not occur entirely voluntarily. Moreover, the nature of peer participation changes developmentally at the time, becoming more complex. The task of making friends and avoiding peer rebuff may be complicated by the dynamics of the early adolescent social climate (Bukowski & Sippola, 2001). In particular, hierarchical social networks and emerging social cliques leave many children either alienated or insecure about their social position (Parker et al., 1995). Almost one-third of 11-year-olds reported losing a friend over the course of the school year (e.g., Wojslawowicz, Rubin, Burgess, Rose-Krasnor, & Booth, in press) and almost two-thirds reported being teased by peers in the previous month (Kanner, Feldman, Weinberg, & Ford, 1987). Ethnographic studies indicate that even popular children and members of cliques experience insecurities about maintaining their reputations and social statuses (Adler & Adler, 1995; Eder, 1985). If children are already vulnerable to social anxiety for other reasons, including distortions in their social cognitions, the inevitable complexity of these normative changes peer experiences may for the first time overwhelm them and make them casualties to social anxiety.

A third principle of developmental psychopathology is that heterogeneity exists across individuals in the nature, precursors, and subsequent course of psychological disorders. Anxiety disorders appear to be consistent with this model of heterogeneity (see Vasey & Dadds, 2001, for relevant reviews). Indeed, the social functioning and peer experiences of children at risk for social anxiety may be characterized by substantial heterogeneity. Thus, whereas compelling evidence links social anxiety and peer maladjustment, not all socially anxious children experience low levels of peer acceptance or suffer victimization by peers. Indeed, the findings of several studies offer evidence for variability in peer adjustment of children with social anxiety. For example, one study of elementary school children found that rejected children were no more socially anxious than average children, and that rejected and average children were more socially anxious than neglected children

(Crick & Ladd, 1993), suggesting that a significant subgroup of socially anxious children may attain average peer status despite their social concerns. Chansky and Kendall (1997) found that anxious children were just as likely to have a best friend as were controls, though they had fewer friends overall.

In addition to the available empirical evidence, there are at least two other reasons to expect heterogeneity in the peer adjustment of socially anxious children. First, socially anxious children as a group may be more motivated than others to gain acceptance and be evaluated positively by peers. The desire for acceptance and belonging is universal (Leary, 2000), but socially anxious children may elevate this desire until it becomes overbearing emotionally. Socially anxious children who are better able to manage emotion in evaluative situations may behave more adaptively than those who cannot, contributing to heterogeneity in vulnerability and outcomes. Relatedly, socially anxious children who possess better social skills, or who are somehow spared salient and humiliating victimization by peers, may weather their vulnerable years with less negative impact than those who lack the behavioral skills to bootstrap themselves out of vulnerable situations or who are somehow spared the most traumatizing forms of peer rebuff.

The concept of *equifinality* is also a point at which the literature on social anxiety may intersect with principles drawn from developmental psychopathology. Equifinality refers to the fact that diverse pathways may lead to the same ostensible outcome. Models of Conduct Disorder that emphasize differences between early- and late-starters are nice illustrations of the principle of equifinality and it is of interest to speculate as to whether parallels exist in the pathways to social anxiety. For example, some children exhibit dispositional and behavioral vulnerabilities from an early age, and thereby reach social anxiety through a long history of continuity. For other children, social anxiety may emerge after a history of positive peer relationships. The onset of social anxiety for the latter but not the former group may be more closely tied to unexpected challenges these children encountered locating a social niche and friendship network following the transition to a new school. Alternatively, some popular children may find themselves overwhelmed with the task of protecting their exalted social status. Thus, it is possible that at least two routes to social anxiety exist: one through a history of temperamental vulnerability, social skill deficits, and peer problems, and another in the absence of such negative developmental canalization. To our knowledge, different developmental models of social anxiety have not been examined empirically, despite the fact that different

courses may have important implications for the stability and treatment of social anxiety.

The principle of *multifinality* suggests that similar conditions at one point in time may lead to different outcomes. Likewise, different responses to social anxiety may also predict different developmental outcomes. In early childhood, those socially wary and inhibited toddlers whose mothers (and fathers) are overprotective and intrusive are observed to be socially anxious and reticent in the peer group as preschoolers; those toddlers whose mothers (and fathers) encourage independence, provide warmth and responsiveness do not appear socially fearful and reticent (e.g., Rubin, Burgess, & Hastings, 2002; Rubin, Cheah, & Fox, 2001). The adolescent and adult outcomes of children with social anxiety may be contingent upon certain responses and coping strategies that promote further decline or resilience. For example, some socially anxious children may be able to manage their negative cognitions and organize their social behavior in a way that minimizes the external visibility and negative social impact of their anxious feelings. For example, by prompting themselves to focus on the conversation rather than themselves during social interaction, some children may reduce self-focused fears of negative evaluation and display more sensitive social interaction skills. Alternatively, by asking questions, socially anxious children may simultaneously validate their partner and remove social-evaluative pressure from themselves.

Finally, the interplay between developmental research and intervention is another well-established feature of developmental psychopathology. Understanding the social functioning and coping strategies of socially impaired and nonimpaired socially anxious children may inform developmental research and intervention. For instance, the social-cognitive and social-behavioral characteristics of children who establish friendships and gain acceptance despite elevated levels of social anxiety may effectively inform intervention for socially anxious children with peer problems. That is, the social-behavioral and social-cognitive characteristics of socially anxious children without significant social impairment may be particularly suitable intervention targets.

FUTURE DIRECTIONS FOR THEORY AND RESEARCH ON CHILDREN'S PEER EXPERIENCES

Developmental psychopathologists have clearly recognized the importance of adjustment with peers in childhood, and have emphasized some of the negative consequences for children of cumulative peer rejection or friendship difficul-

ties. Even so, it can be argued that developmental psychopathologists have not taken full advantage of many of the insights of researchers who have studied children's peer relationships from outside that framework. Yet, research on children's peer relationships can in some ways be seen as paradigmatic of the developmental psychopathology approach. For example, one of the guiding propositions underlying a developmental psychopathology perspective is that individuals develop both toward increasing flexibility and increasing organization (Cicchetti, 1990; Sroufe & Rutter, 1984). This proposition aptly characterizes the pattern of development in several areas of children's peer relationships, such as the growth of children's conceptions of friendship and the developmental patterns in very young children's play. Another example is the concept of directedness, encompassing the idea that individuals selectively receive, respond to, and create experience based on past experiences and cognitive frameworks and biases. As we reviewed, much attention within the literature on children's peer relationships has been directed toward the biases and inappropriately selective social information processing of children with peer relations difficulties; we are beginning to learn how such biases contribute to individual differences in peer interaction and exacerbate the problems of certain children with budding peer relationship difficulties. As a final example, the evidence that we reviewed presented a convincing case for viewing disturbed adjustment to peers as a condition of risk. However, peer rejection has very seldom been included among the litany of illustrative risk conditions (e.g., Down's syndrome, maltreatment, failure-to-thrive, insecure attachment, depression) that are commonly cited by developmental psychopathologists (cf., Cicchetti, Lynch, Shonk, & Manly, 1992).

For their part, investigators seeking to understand children's relationships with peers have not often done so explicitly within a developmental psychopathology framework. There are signs this is changing (Cicchetti & Bukowski, 1995). For example, in 1995 a special issue of the journal *Development and Psychopathology* was devoted to exploring this interface and featured, among many other notable topics, reports on the peer experiences of children with Attention-Deficit Hyperactivity Disorder (Hinshaw & Melnick, 1995) or Autism (Lord & Maggill-Evans, 1995); the predictive outcomes of social withdrawal (Rubin, Chen, McDougall, Bowker, & McKinnon, 1995), and reports on the longitudinal stability of aggression and peer rejection (Bierman & Wargo, 1995; Burks et al., 1995; Coie et al., 1995). Another encouraging exception is emerging work on the peer experiences of maltreated children (e.g., Bolger & Patterson, 2001a, 2001b; Levendosky, Okun, & Parker,

1995; Parker & Herrera, 1996; Rogosch, Cicchetti, & Aber, 1995). Many features of maltreating families are believed to inhibit the development of competent peer relationships in abused children. A better understanding of maltreated children's peer experiences can provide developmental psychopathologists with insights into how such a profound disturbance in parent-child relationships affects the cognitive, affective, and behavioral systems of abused children. For peer relationships researchers, however, the study of maltreated children's friendships and other peer experiences can, among other things, be used as test assumptions about the role of specific skills or formative experiences in adaptive peer interaction or the development of successful friendships. Notwithstanding these encouraging exceptions, most work on children's adjustment with peers has remained somewhat disconnected from the interpretive framework and tenets of developmental psychopathology. In our view, the framework of developmental psychopathology can sharpen our understanding of some of the new and well-established findings in this area, as well as reveal directions for future work.

Accordingly, we close with several suggestions for directions for future research inspired by our reading of the state of the literature on children's peer adjustment and relationships.

Giving Context Its Due

The literature on children's and adolescents' peer adjustment remains a literature dominated by a focus on the dispositions and behavioral inclinations of individuals. For example, most of the normative developmental changes we described are assumed to have been driven by age-linked advances in individuals' language, social-cognition, and emotion regulation skills. This is the case, for example, concerning the growth children display over the early years in the complexity of their play. For the most part, cognitive, language, and affective achievements in individuals have been assumed to be responsible for the appearance of novel and more advanced forms of play with age. The bias toward dispositional explanations is not limited to normative changes however. We saw it repeatedly in the representation of individual differences, where the pervasive assumption is that differences in temperament, social cognitive and affective skills, and behavioral tendencies account for why some children are more readily rejected by peers and remains so over time.

Dispositional assumptions have contributed greatly to our understanding of the nature of developmental changes and individual variability in peer experiences. However, echoing sentiment expressed by earlier authors (e.g., Fer-

guson & Cillessen, 1993; Higgins & Parsons, 1983), our hope is that future research in this area will balance this dispositional approach with a better understanding of the organization and nature of contextual factors. As a simple start, greater attention should be devoted to documenting the contexts in which children and adolescents interact with their peers outside of school (e.g., Mahoney, Larson, & Eccles, 2005). Our understanding of children's peer experiences has been heavily shaped thus far by studies of children in school settings. Notable exceptions include efforts to understand the "subjective landscape" of adolescent activities (e.g., Kirshner, O'Donoghue, & McLaughlin, 2002; Laursen & Koplas, 1995; Morrissey & Werner-Wilson, 2005; Richards et al., 1998), the interaction opportunities afforded by different activity contexts (Benenson, Maiese, et al., 2002; Beneson, Markovits, Roy, & Denko, 2003; Beneson, Markovits, et al., 2002; Mahoney, Larson, & Eccles, 2005; Zaratany et al., 1990), and the formal and informal sources of interpersonal support available to children in their neighborhoods (Bryant, 1985). A more complete catalogue of the settings in which children interact with peers at different points in development is essential to understanding the social challenges facing children, how peer experiences influence children, and why some children are more successful with their peers than are others.

There are other ways in which the field will benefit from fuller treatment of context, however. One of the most important would be increased understanding of the emergence, maintenance, and consequences of victimization and rejection by peers. Differences in group expectations and norms influence to a powerful extent the acceptability of specific behaviors (Boivin, Dodge, & Coie, 1995; Bukowski & Sippola, 2001; Salmivalli, 2001). For example, the general conclusion that aggression is strongly linked to group rejection masks some important contextual variability. In particular, because peer attitudes toward specific behavior are affected by group norms, some evidence suggests that aggression is less strongly linked with group rejection in group contexts where aggression is more normative (e.g., Boivin et al., 1995; Stormshak, Bierman, Bruschi, Dodge, Coie, & the Conduct Problems Prevention Research Group, 1999; Wright, Giammarino, & Parad, 1986).

Additionally, earlier we noted the self-perpetuating nature of children's reputations with peers, stressing that, once in place, group reputations tend to become self-fulfilling in that they elicit from children behavior consistent with peer expectations. Group reputations, then, are important contextual factors in behavior. Yet, to date, because the emphasis has been so heavily focused on child characteristics (e.g.,

social problem-solving skills, emotion regulation difficulties, attribution biases) group expectations rarely appear in our models of the determinants of behavior.

The context of behavior also includes the relationship history between individuals; The incorporation of relationship histories into models of behavior would also represent a significant advance. This type of approach is already yielding dividends, albeit to date in largely isolated corners of the literature (e.g., Parker & Herrera, 1996; Roy & Benenson, 2002). For example, the identification of aggressive children is a cornerstone of research in children's peer adjustment and a great many conceptual models have been offered as to why some children are more aggressive with peers than are others. It is widely recognized but only seldom acknowledged in these models that individuals are not indiscriminately aggressive. Instead, the social histories between any particular pair of children appears to play an important role in whether they are aggressive toward one another and relational histories account for much of the aggression that occurs within groups (Burgess et al., 2005; Coie et al., 1999; Hubbard et al., 2001). Likewise, the development of mutual animosity between specific peers appears to depend more on their specific disagreeable history together than on either individual's tendency to be disagreeable in general (Parker & Gamm, 2003). As these examples illustrate, without attention to the relational context, it may be difficult to understand individual behavior (Hinde, 1987, 1995).

Consideration of context also begs the question of culture. It is probably the case that in some cultures, the construct of popularity has little meaning; Rather than being well liked, the respect of peers may carry much of the weight in determining later outcomes. Furthermore, those who are disrespectful of adults (and peers) may be the individuals, in collectivistic cultures, who prove most shameful to their families and friends; and it may be that these disrespectful children (e.g., those who do not demonstrate "hyo" or filial piety in Asian cultures) are the ones at greatest risk for later negative outcomes (Rubin, in press). Insights into issues of this type have been occurring (e.g., Casiglia, Lo Coco, & Zappulla, 1998; X. Chen et al., 1995, 2004; Deater-Deckard & Dodge, 1997; Hamm, 2000; Khatr & Kupersmidt, 2003; Killen, Crystal, & Watanabe, 2002), but progress lags.

As a final example, we draw attention to the potential moderating role that context may play in judging the consequences of group rejection and victimization. Earlier we reviewed evidence suggesting that victimization by peers is associated with subjective distress in victims. This find-

ing has received wide and well-deserved attention and many authors point to it as the basis for justification of intervention on behalf of victimized children. Without disputing the general conclusion, however, it is worth noting that this relation is less robust than might first appear. In particular, there is evidence that the social context of victimization plays an important role in moderating the extent to which victimization is accompanied by distress. Bellmore, Witkow, Graham, and Juvonen (2004), for example, have shown that victimization is associated with the highest levels of personal distress in classroom contexts in which the victim shares the ethnicity of many of his or her classmates. Mitigation of personal distress appears to occur in classroom contexts in which the victim is in the ethnic minority, presumably because the victim is able to dismiss the victimization by peers as racially rather than personally motivated.

Expanding the Scope of Focal Outcomes

The premise that children with relationship problems are at risk for later life difficulties is a widely shared professional and popular belief and has played an important role in motivating research on children's adjustment with peers. Evidence in support of this premise is not easy to obtain, but, as we have reviewed, it is mounting and persuasive (see also Nangle & Erdley, 2001). Even a cursory appraisal of this literature, however, reveals some narrowness, insofar as the outcomes of primary interest largely include subsequent school failure, later involvement in delinquent or adult criminal behavior, and a variety of indications of later mental illness and psychopathology. Problems in these areas are significant and are the focus of considerable public, private, and institutional concern. Thus, an effort to examine whether early negative experiences with peers can place individuals at risk for such significant disturbances is wholly appropriate and merits continuing. At the same time, we suggest that the opportunity exists for expanding the scope of the search for the later implications of earlier successful versus unsuccessful peer experiences. In particular, we suggest that the field would be well served by future research designed to uncover logical continuities in the interpersonal adjustment of individuals during the periods from childhood to emerging and later adulthood.

In many instances, this search will direct attention to outcome variables that are far more subtle than the dramatic, psychopathological outcomes so prevalent in past work. As an example, we reviewed evidence that has emerged recently suggesting that certain, vulnerable chil-

dren display undue and unwarranted jealousy surrounding their best friends (Parker et al., 2005). Friendship jealousy is a source of considerable personal distress for these children and other evidence suggests that it is also at the root of a good deal of the aggression and victimization that occurs within peer groups. Jealousy, of course, is a more familiar topic in the study of adults in romantic contexts, where it is recognized as a major contributor to relationship dissatisfaction (e.g., Anderson, Eloy, Guerrero, & Spitzberg, 1995) and relationship violence (Hansen, 1991; Stets & Pirog-Good, 1987). In view of evidence that the disposition to jealousy is rooted in distorted perceptions of the self and others (see Parker et al., 2005), it would not be surprising if future research revealed that the children who display jealousy surrounding friends in middle childhood are also the individuals responsible for the bulk of the jealousy in adult romantic contexts. In addition to being of predictive and applied significance, confirmation of this longitudinal relation could also contribute to broader debates concerning the nature of the link between the friendship and romantic interpersonal contexts (e.g., Connolly, Furman, & Konarski, 2000; Furman, 1999; Furman et al., 2002; Laursen & Williams, 1997; Seiffge-Krenke, 2003). Other possible areas in which continuities seem likely include links to occupational adjustment and advancement, marital adjustment, difficulties of affect regulation, to name only a few.

Last, many, if not most of the longitudinal research on children's peer relationships has focused on negative outcomes. There has been very little work on the predictors of adaptive, functional outcomes in adolescence and adulthood.

Revisiting Competence and Incompetence

In much the same way that the search for the outcomes of negative peer experiences has focused on the dramatic, it is also the case that researchers have focused on "big-ticket" constructs in their search for the interpersonal behaviors that contribute to peer rejection and other negative peer experiences. But impulsive behavior, aggression, and social withdrawal are not the only predictors and concomitant correlates of peer rejection. More subtle contributors to peer experiences deserve attention as well. Indeed, almost all behaviors that cannot be considered normative to particular groups, contexts, and cultures, should be considered candidate behaviors for study in those contexts. An important direction for the future is to design studies that permit us to learn whether these subtler behaviors are also competencies and are as likely to predict, not only peer rejection,

but also more extensive maladaptive developmental trajectories as the "big ticket" items that have been the focus in the past (Rubin, in press).

Further Exploration of Family-to-Peers Linkages

Research concerning the family processes that contribute to adjustment in the peer group has blossomed conspicuously recently, so much so that this area of inquiry should surely be counted among the handful of areas demonstrating the most significant inroads in the decade since our last review. We did not review this literature here, but comprehensive reviews are available (Ladd & Pettit, 2002; Parke & O'Neill, 1999; Rubin & Burgess, 2002). In our view, however, some unevenness in progress is evident in this area. In particular, we appear to know more about those family experiences leading to aggression, withdrawal, and peer rejection than we do about family processes that lead to social competence, peer acceptance, and the ability to form and keep qualitatively rich friendships. How children come to develop the abilities to join others in play; make friends; engage in cooperative group endeavors; mentor younger peers; demonstrate loyalty to friends; learn how, when, and to whom one should self-disclose; forgive those who have purposely or inadvertently harmed them; and so on, are topics that do not leave a lengthy trail of published developmental products. Especially lacking are process approaches to the study of parent-child linkages. Most research is organized around the outcomes of such negative parenting practices as harsh punishment, intrusiveness, over-directiveness, and over-control, and guilt induction. And almost all research on family links to peer interaction, relationship, and group endeavors is drawn from studies carried out in prototypically "western" cultures. This is certainly an area in need of attention. Once again, it behooves researchers to consider how social competencies and adaptation develops; to do so would allow strong conclusions to be drawn on how incompetencies and maladaptation become manifest.

Toward an Integrated Representation of Adjustment with Peers

At the outset, we noted that the past decade has been one of unprecedented advances in the development and refinement of methods for studying adjustment with peers. Whereas this rapid expansion has increased the range of methodological options available to researchers seeking to represent

children's adjustment with peers, it has not produced an overarching framework for considering when specific measures are preferable to others or how multiple measures are related. We noted that adjustment with peers appears to have at least two primary dimensions of individual differences—success with friends and acceptance by the peer group. A wide array of measurement options are available within each of these ways of representing peer experiences. Yet, for the most part, very little is confidently known about how these broad dimensions should be integrated or how the measurement options available within each dimension relate to one another or across dimensions.

Increased recognition of the links between friendship and group experiences appears to us to be an especially important direction for future research. Group level processes, such as those that dictate which individuals are central versus peripheral members can exert important constraints on the possibilities for friendships among members of groups. At the same time, the bonds of friendship also provide children with access to membership in selected groups (see Sabongui et al., 1998). Likewise, by serving as the broader context in which friendship experiences unfold, groups and social networks presumably shape children's experiences within friendships in significant ways. On the one hand, outsiders can have a positive influence on friendships (see Milardo & Helms-Erikson, 2000). For example, group interaction is more enjoyable in certain ways than dyadic interaction and third parties can act as mediators to resolve disputes between friends. Nonetheless, outsiders can also be significant sources of trouble for friends (Asher et al., 1996). For example, outsiders may preempt opportunities for frank discussion between friends and coordination of social activities may be more complicated and less satisfying in groups larger than two (Benenson et al., 2001; Benenson, Maiese, et al., 2002; Lansford & Parker, 1999). In addition, tension and conflict can arise between friends if participants are squeezed between their loyalty to their friend and the obligations to others (Asher et al., 1996; Selman, 1980).

To some extent, answers to how measures might be integrated should come as researchers gain more experience with data sets that include many alternative assessments and permit examination of their interrelations. But we also encourage future researchers to think conceptually concerning this issue. Hinde (1979), as one example, has encouraged researchers to consider dyadic-level assessments, such as those that identify friendships, and group-level assessments—such as those that can give rise to appraisals of acceptance or rejection—as bearing a hierarchical, and mutually influential relation to one another.

CONCLUSIONS

After initial experiences with parents and siblings, children enter into increasingly complex relationships with peers. In this chapter, we have reviewed evidence that children's experiences with other children are significant to their growth and adjustment. We have reviewed some of the ways in which peer experiences complement children's experiences with family members, particularly parents, and some of the ways in which peer experiences may be unique experiences in development.

Much of the chapter was devoted to considering the wide individual variability in children's peer experiences, which we suggested could be organized powerfully along two basic dimensions—success with friends and acceptance by the peer group. Consideration of friendship adjustment suggested both qualitative and quantitative aspects that may be linked to developmental processes and outcomes. At the acceptance level, we considered especially the child's membership in sociometrically identifiable status groups. Evidence was found for the validity of parsing children's social world into such categories; members of different sociometric groups show distinct behavioral profiles, for example. Additionally, we devoted attention to the reciprocal intrapersonal and interpersonal processes that give rise to variability in peer adjustment and to the implications of peer adjustment for short-term and long-term psychopathology. Finally, we concluded by suggesting several areas that could be prosperous areas of future research. These topics suggested themselves to us from our perspective of considering how far and in what directions the decade of research since our last review has taken us. As this discussion makes abundantly clear, there are sufficient challenges remaining in the study of children's peer experiences to keep researchers and theorists busy well beyond a further decade.

ACKNOWLEDGMENTS

We gratefully acknowledge the contributions to this chapter of our many wonderful collaborators and coauthors over the years. We are also grateful to Dante Cicchetti for this opportunity and for his instructive feedback and patience concerning the original as well as this revised version of the chapter. Finally, we are indebted to Sarah Kollat for her invaluable assistance identifying and locating pertinent literature and to Corrine Farinola for her tireless assistance tracking and typing references.

Structural Policy and Resource Effects at Building and District Levels	512
Proximal Process Effects: Classrooms, Teachers, Peers	514
Macroregulations: School Transitions	519
Summary	521
CONCLUSIONS, IMPLICATIONS, AND FUTURE DIRECTIONS	522
REFERENCES	524

Understanding the nature and course of development is inextricably linked with our understanding of adaptation in school and schooling's effects on adaptation. A focus on school effects and adaptation to school has been a part of the field of developmental psychopathology since its inception (see Rutter & Maughan, 2002; Sroufe & Rutter, 1984). Within developmental psychopathology, there is little doubt that schools are settings for assessment of adaptive and maladaptive behavior patterns and sources of influence on those patterns, as is well-documented in reviews of descriptive research and intervention trials (e.g., Eccles & Gootman, 2002; Greenberg, Domitrovich, & Bumbarger, 2001; McMahon & Washburn, 2003). In the past 2 decades, with

the rise of contextualism in developmental science (Cicchetti & Aber, 1998; Lerner, 1998) and the focus on positive development in community settings (Connell, Kubisch, Schorr, & Weiss, 1995), schools have become places of even more interest to developmentalists (e.g., www.cfchildren.org). However, notwithstanding the extensive developmentally informed programs of research on schooling and its effects that have been reported in the past 10 to 15 years (e.g., Alexander & Entwisle, 1988; Eccles & Roeser, 1998; Ladd & Burgess, 1999; Morrison & Connor, 2002; C. T. Ramey et al., 2000; Stevenson & Lee, 1990), the links between developmental psychopathology and education are far from systematic or programmatic.

Deepening, extending, and more fully integrating the study of developmental psychopathology, school effects, and school adaptation is the goal of this chapter. Because the challenges to integration are fundamentally conceptual, the primary goal of the chapter is to articulate and advance a set of conceptual frameworks that can serve as tools for integrative research. Throughout, empirical work is used illustratively. In the end, the chapter points to the value for both disciplines of reconceptualizing the link between education and developmental psychopathology.

The work reported herein was supported in part by the National Center for Early Development and Learning under the Educational Research and Development Centers Program, PR/Award No. R307A60004, as administered by the Office of Educational Research and Improvement, U.S. Department of Education. It was also supported by the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care (U10-HD25449) and NICHD R21-43750. The contents do not necessarily represent the positions or policies of the Office of Educational Research and Improvement, the U.S. Department of Education, or the NICHD, and endorsement by the federal government should not be assumed.

The chapter is organized into four sections. The first outlines the mutual interests of developmental psychopathologists and educators and points out theoretical and practice gains that could be the result of strategic exploitation of these interests. The second section discusses conceptual barriers to interdisciplinarity between developmental psychopathology and education and suggests an alternative, integrative perspective. The third section presents a model of schooling and the factors related to school effects and adaptation that have been identified in the literature. This section provides a map of school factors that link well to developmentally informed studies of social and behavioral outcomes. Finally, the fourth section identifies a set of integrative conclusions and future directions for further work. One way to look at the first three sections is as a discussion of three related questions: What contributions can developmental psychopathology and education make to one another? What broad conceptual principles should guide interdisciplinary integrations? What are the facets of schooling and its organization of interest to developmental psychopathology?

MUTUAL INTERESTS OF EDUCATION AND DEVELOPMENTAL PSYCHOPATHOLOGY

Across most Western societies, children are exposed to formal schooling experiences starting sometime between the ages of 4 and 7 and ending anywhere between 10 and 12 years later, longer when post-high school education is involved. Along the way, substantial developmental change routinely occurs, in part as a function of experience in school. Schools are *designed* to intentionally, formally, and strategically direct the nature and course of these changes in many areas of functioning. Schools were, and still are, conceived as a society's investment in the future; they serve to secure certain social values and provide for the future welfare of a society's citizens. In a manner that is far from trivial, schools are often viewed with the same value-laden lens as families, and just as often the same responsibility for children's and society's welfare as is attributed to families is attributed to schools. When schools are viewed as having a compensatory role in relation to family risks and liabilities (e.g., Duncan & Brooks-Gunn, 1997; Gambone, Klem, & Connell, 2002), then arguably, greater social importance is being attributed to educational settings than to the family.

From its inception, the field of developmental psychopathology has had a connection to schools, schooling, and

educational outcomes and processes. A landmark study in the field, the Isle of Wight study (Rutter, Maughan, Mortimore, Ouston, & Smith, 1979), was closely concerned with the role schools play in accounting for the differences in mental health and behavioral outcomes observed among the study participants. This interest in schooling grew into the classic *Fifteen Thousand Hours* study of secondary schools and the resultant attention to such facets of schooling as leadership, focus, organization, and teacher qualities (Rutter, 1982; Rutter et al., 1979).

Developmental psychopathology's interest in schools 25 years after *Fifteen Thousand Hours* remains strong. Rutter and Maughan (2002) conclude their recent summary of progress in research on schooling and development since that study by acknowledging a series of questions that informed their original work and that continue to press for attention. These questions involve

1. The need for hard empirical evidence on factors related to changing failing schools, including attention to contextual features (such as community attitudes), resources (intake mix), teacher recruitment, finances, and leadership;
2. Peer processes and influences within schools;
3. Characteristics of schools that matter for social, behavioral, and self-efficacy outcomes;
4. How schools foster connections to the goals of schooling and socialization;
5. How selective and nonselective school systems function to influence child outcomes;
6. How different experiences in schools affect children differently based on their pattern of strengths and limitations, and vice versa; and
7. How and why children respond so differently to the school environment.

What is notable about these questions, apart from their cogency in summarizing the state of the field in educational research, is that, as a group, they fit so harmoniously within a developmental framework or paradigm. They reflect an interest in contexts and processes, in individual differences as well as normative growth, in multiple domains of functioning, and in multilayered systems co-acting across time. These are the core interests of many developmental scientists and they are here reflected in questions about experience and adaptation in school settings in ways that parallel the work already conducted, addressing analogous questions in family and child care settings. One might argue that these questions invite an

extension of the *development in context* paradigm beyond its historical application to the period of infancy to pre-school and into the school years.

Opportunities for Developmental Psychopathology

Recent decades of school reform (National Center for Education Statistics [NCES], 2003) illustrate the role that schooling is intended to play in American society at the outset of the twenty-first century. It is increasingly clear that schools and formal education are indeed viewed as agents of equity and access in American life, and the perceived, and realized, inability of schools to successfully function in this manner is responsible for widespread reform efforts initiated at federal, state, and local levels over the course of the past 20 years. The reform movement has crystallized the many roles schools play in addressing children's needs: Schools now strategically deliver preventive interventions to at-risk populations, have a clear role in defining and measuring adaptive functioning and pathology, and are the major provider of mental health services to children. These roles for schools provide natural links to developmental science that can be exploited in ways that advance understanding of development and support developmentally informed programming for children (e.g., Pianta, Hamre, & Stuhlman, 2003).

School Reform and Indicators of Adaptation

In almost all cases of school reform, goals germane to developmental psychopathology are explicitly stated in legislation and policy and operationalized in practice (NCES, 2003). Gambone, Klem, and Connell (2002), in their study of several integrated databases pertaining to adolescent development and young adult outcomes, identify the links between social and academic experiences for which schools are often responsible and adult functioning. In this analysis, the opportunity to engage challenging and engaging learning experiences that expand skills and competencies and to experience supportive relationships with non-parental adult figures is identified as fundamental to broad adaptational functioning in social and interpersonal relationships, employment, and emotional health and personal well-being. In nearly every community, schools are the primary nonfamilial conduit for the provision of these experiences and opportunities (NCES, 2003). It was in part due to concerns related to the attainment of broad, adult goals of economic self-sufficiency, healthy family and social relationships, and involvement in the community that attention turned to the failure of schools to produce these

outcomes and spawned the reform movement. As a consequence, in a much more formal way than 20 years ago, schools are both community resources and arbiters of metrics for success and failure, functions of interest to developmental psychopathology.

The recent No Child Left Behind Act (NCLB, 2001; NCES, 2003; <http://www.ed.gov/nclb/landing.jhtml?srac=pb>) is a federal initiative designed to hold schools accountable for their performance or production relative to society's needs and advances, a particular definition of accountability and outcome based on performance on standardized achievement tests. In 49 states, some form of accountability tests exist, many extending down to the third grade and most functioning to create successive skill-focused hurdles that children and youth must clear to graduate (NCES, 2003). Great debates have taken place over the use of performance on standardized achievement tests as the metric for school adaptation, with arguments against testing as the sole indicator of success resting on the need to conceptualize, value, and assess success in terms of social and interpersonal relationships, motivation and a sense of personal competence, and mental health and emotional well-being (Berliner & Biddle, 1995). To this point, in no state has a broader definition or assessment of school adaptation found its way into the accountability mechanisms (NCES, 2003). To the extent that some degree of broadening beyond academics has occurred, it is evident in the work on the Head Start National Reporting System (the accountability plan for Head Start programs), which has planned a pilot implementation of teachers' ratings of children's social functioning; the Technical Work Group affiliated with this effort is discussing direct assessment of self-regulation (Administration for Children and Families [ACF], 2003). One contribution of developmental psychopathology to education would be articulation of the ways in which social, emotional, and mental health outcomes are tied to the same long-term adult goals that schools aspire to fulfill (Eccles & Gootman, 2002; Gambone et al., 2002) and thus to provide empirical evidence for alternatives to defining school adaptation in terms of test performance.

Broad legislative initiatives aimed at improving the functioning of the child, adolescent, and adult populations as a consequence of improving schools have in turn created a set of ancillary policies that themselves have implications for developmental psychopathology. The combination of school-defined and -measured indicators of adaptive functioning, as well as schools functioning as a community's mechanism for promoting adaptive functioning in children and adults, has, at times, resulted in a system in which

adaptive failure is created as a consequence of shifts in educational policy or practice (see Berliner & Biddle, 1995). Consider, for example, the current situation in Virginia and several other states, where the legal age for dropping out of school (an identified risk factor for subsequent un- or underemployment and substance use) was recently lowered, making it permissible for youth to disengage from formal schooling at age 15 instead of 16. Recent state reports indicate quite clearly that as high-stakes consequences are attached to performance on school accountability tests, an increasing number of youth (most with a history of academic failure) take advantage of this type of early dropout policy (Berliner, 2004). In this way, educational policy and accountability tests designed to increase school success conspire to exacerbate risk.

As another example of educational policies with implications for defining adaptation, every school in the country is required to screen its population of children and provide special education for those with a range of disabling conditions, including disorders related to learning and behavior. Arguments have raged for at least the past 2 decades concerning the use of various cutoff indicators and definitions to delineate and identify children with disabilities from other children struggling to perform well in school (see Ysseldyke, Algozzine, & Thurlow, 2000). Legislative and policy changes in response to these arguments create new classes of children “with” and “without” disabilities on a regular basis. These categories are an operationalization of adaptive and maladaptive functioning in the same way that systems of psychiatric nosology provide a set of descriptors for marking developmental success and failure. The educational and psychiatric nosological systems serve both scientific and service-delivery purposes. If these systems were superimposed on one another and examined in relation to an assortment of information on child functioning in school, community, and home contexts, opportunities are opened for understanding adaptive function from a range of perspectives. Typically when such efforts are conducted, a far more differentiated and contextualized vision of function is evident (Noam, Warner, & Van Dyken, 2001; Rones & Hoagwood, 2000).

Early Intervention and Prevention: The Dynamics of Community Action

Theoretical frameworks in developmental psychopathology have for some time emphasized the multilevel nature of systems that regulate developmental processes and outcome (Cicchetti & Dawson, 2002; Gottlieb & Halpern, 2002). Schooling provides developmentalists with opportunities to examine multilevel interactions given its layered

nature of community, site, classroom, teacher, and peer influences (Eccles & Roeser, 1998). Interest in promoting the functioning of the youngest children in school has in recent years been intense, again with implications for developmental psychopathology. The emergence of an entirely new service sector in schools—programs for (at-risk) 4-year-old children—has in part been the consequence of this interest (Bryant et al., 2003), stemming from developmentally oriented research showing both the critical importance of the early school years and the value of high-quality early intervention programming (e.g., see C. T. Ramey et al., 2000; C. T. Ramey & Ramey, 1998). The prekindergarten sector in public schools now serves well over a million children, mostly from low-income families and most at risk for problems in learning, behavior, and socioemotional development (Clifford, Early, & Hills, 1999). These programs are state-funded interventions for high-risk children (and sometimes their families) that have explicitly stated goals to enhance both academic and social/interpersonal success in school. Systematic, developmentally informed study of the processes by which these state prekindergarten programs and federally supported Head Start programs alter social and academic trajectories, promote resilience, and prevent problem outcomes (e.g., Bryant et al., 2003) exemplifies integration of developmental psychopathology and education that has implications for both disciplines.

For example, developmentally informed examination of the specific aspects of prekindergarten classroom experience related to growth in social and academic functioning in prekindergarten (Howes et al., in press) clearly points to the critical importance of both emotionally sensitive and intentionally instructional interactions on the part of teachers in these classrooms. These results have initiated efforts to understand the key aspects of teachers’ training, knowledge, and experience that contribute to their sensitivity and intentionality, integrating developmental study with teacher education and professional development (Institute of Education Sciences [IES], 2004a; Pianta, 2003; Ready to Teach Act, H.R. 2211, 2003). Through this type of integrative inquiry, developmental psychopathology gains knowledge about the function of parameters in school settings that affect children’s social and behavioral adjustment that can inform both theory and the design of interventions, while education benefits from analysis of school effects in large samples of children in which links between policy and outcome are evaluated in light of classroom processes. To the extent that standardized metrics of child functioning and classroom process are embedded in intervention programs such as those for prekindergarten

at-risk children, or such as those proposed for Head Start (ACF, 2003), opportunities for further elaboration of community-school-classroom-home effects on children's adaptive functioning will emerge at the population level.

With regard to children's mental health outcomes, because they are public institutions in which nearly an entire community participates, schools frequently are the focus of efforts to promote mental health and reduce risk both at local levels and as reflected in national policy (Cowen, 1999; Rones & Hoagwood, 2000). Schools are often the locus of efforts to improve children's physical health and well-being and the single most frequently mentioned context as a site for mental health intervention (Hoagwood & Johnson, 2003; Nastasi, 1998). To quote Rones and Hoagwood, "It is now well documented that, insofar as children receive any mental health services, schools are the major providers" (p. 223). Almost a decade ago, Durlak and Wells (1997) found that 72.9% of all studies of prevention trials involving children took place in schools, with 20% of change agents being the child's teacher(s), a trend that has noticeably increased (e.g., Illinois General Assembly, SB 1951, 2003). Developmentally oriented applied psychologists are now advancing the position that developmental psychopathology and schooling become more formally linked through reforming clinical child psychology and school psychology as public health professions (Hoagwood & Johnson, 2003). Alternatively, educators have started to include developmentally informed conceptual frameworks in discussions of classroom management and teacher training initiatives that are intended to address children's behavioral and emotional needs (Evertson & Weinstein, in press). Clearly, the linkage of schooling and mental health is moving beyond add-on programs and social skills groups toward more complete integration at the conceptual and operational levels, as evinced by embedding support resources to teachers and reforms in teacher education Ready to Teach Act (H.R. 2211, 2003), as just one set of examples. In a larger, integrative conceptual frame, schooling can be viewed as a community-level action aimed at promoting mental health and can be studied as such (Rutter & Maughan, 2002).

Challenges in Moving toward Integrative Scientific and Programmatic Efforts

The ways schools function at federal, state, and community levels to deliver preventive interventions to at-risk populations, their role in defining and measuring adaptive func-

tioning and pathology, and the very specific role they play as a major provider of mental health services are so compelling that we might conclude that prevention science, developmental psychopathology, and educational, clinical, and school psychology strategically launched integrative science and practice initiatives related to school adaptation and schooling processes. This is far from the case, and strategic integrations of these overlapping fields are the exception rather than the rule. Rones and Hoagwood (2000) note:

The inattention in the scientific literature, even at a descriptive level, to identifying types, intensities, dose, or quality of preventive treatment services in schools is surprising . . . it is surprising that so little attention has been given to the effectiveness of school programs targeted toward prevention, reduction, or treatment of mental health problems. (p. 223)

Even less attention is paid to the ways in which daily, routine interactions between teachers and children, or among peers, function as developmental assets or risks, or the ways in which school policies and procedures shape the value of such interactions on a day-to-day basis.

Implied in this quote is the absence of conceptual, research, and programmatic linkages between the education research, policy, and practice establishments and developmental psychopathology. Particularly from the perspective of research design and conceptualization, the overlap and integration of education science and developmental psychopathology is far from realized, thereby undermining a more sophisticated understanding of developmental process and outcome and the manner in which schooling intersects with and contributes to those processes and outcomes. Pianta (2003) argues that one reason for the gap between developmental research and theory and education is that developmental scientists have rarely ventured into school settings with the goal of understanding the dynamics of schools and the way they intersect with developmental processes. Unlike child care and afterschool settings, the nature, quality, and effects of which have been well described and studied *within* developmental frameworks (e.g., National Institute of Child Health and Human Development Early Child Care Research Network [NICHD ECCRN], 2002a), school settings have not been as fully integrated in developmental research frameworks and studies. Despite the importance of contextualism in developmental science (Cicchetti & Aber, 1998; Sameroff, 2000), too often schools are treated simplistically in developmental psychopathology research. They function as loca-

tions for gathering large samples of children, as contexts in which outcomes of interest can be assessed (often cheaply), or as sites onto which intervention techniques can be grafted or applied. For their part, educational researchers and theorists have developed sophisticated understandings of schools as complex, multilevel settings, but have yet to fully integrate into that understanding an equally sophisticated understanding of human development, instead relying on outdated or oversimplified stage theories or conditioning as explanations of change and growth (see Meisels's 1999 critique of readiness definitions) or focusing exclusively on narrow conceptualizations of functioning such as is reflected in standardized test performance. The lack of full incorporation of school settings into developmental frameworks is reflected in developmental psychopathology's struggle with three challenges: (1) understanding the wide variation in implementation of standardized mental health or behavioral interventions, (2) including schooling processes in longitudinal studies, and (3) understanding how reliance on informant-based outcome assessments hold potential for misinterpretations and their reification.

Moving from Programs to Processes

Although developmental psychopathologists have arguably made great headway in identifying key ingredients of school settings that, when systematically altered, can provide preventive supports for children (Greenberg et al., 2001), it is also the case that if such efforts are to be realized in terms of reaching children in need on a widespread basis, then attention to the basic processes of schooling and the infusion of clinical trial-derived knowledge into those processes is key (Greenberg et al., 2001; Rones & Hoagwood, 2000). In the academic arena, this progression is evident in the shifting of attention over the past decade from a search for evidence-based curriculum, to a focus on processes related to implementation of curriculum, to recent calls for research on teacher training mechanisms that support high-quality implementation (IES, 2004a). This is a movement from program to process.

In conclusions drawn from their comprehensive review of school-age (and mostly school-based) prevention efforts, Greenberg et al. (2001) noted the need to focus attention on qualities of the school environment that moderate intervention effects and account for the high levels of interindividual variability in response to standardized clinical trial interventions. Understanding and ultimately harnessing factors related to program or practice *implementation* (another term for interindividual variability) is a serious chal-

lenge to developmental psychopathologists' intervention and prevention work. Large amounts of accrued evidence suggest that even the most well-described, manualized, standardized, scientifically based programs are enacted in practice in ways that vary widely from child to child and classroom to classroom (e.g., Greenberg et al., 2001). This phenomenon could be responded to as a source of error in evaluation studies, as an obstacle to delivering mental health resources to children, or as an aspect of the context into which interventions are being inserted that warrants attention in its own right. This last response is consistent with the movement from programs to processes that has occurred in some domains of academic achievement in relation to renewed attention to teacher education.

Not surprisingly, Rones and Hoagwood (2000) conclude that there is so little exploration in clinical trial research of the quality of, and factors related to, implementation, that it greatly impedes the provision of supportive services to children. They extend this position into a call for research on implementation that fully integrates mental health intervention program content into general classroom curriculum and processes. Roeser, Eccles, and Sameroff (2000, p. 466) extend the linkage between developmental studies and education even further when arguing, with respect to understanding middle school effects, that the need is for research "linking the study of adolescents' experience, motivation, and behavior in school with the study of their teachers' experience, motivation, and behavior at school." Such a perspective directly addresses the interindividual variability observed in standardized clinical trial interventions by making variation in psychological and behavioral processes of the child *and teacher* a legitimate focus of study.

The lack of an integrative, process-focused research agenda related to socioemotional adaptation in schools and school effects is in part responsible for the often-reported conclusion from reviews of intervention and prevention programs that implementation processes account for significant variation in the efficacy of such efforts (Greenberg et al., 2001; Rones & Hoagwood, 2000). Implied in the conclusions drawn by Greenberg et al., in their comprehensive review of programs for preventing mental disorders in children, is the impression that if such programs are to go to "scale," then one of the key steps will be to establish mechanisms for implementation in the natural systems in which children come into contact with developmentally salient resources—primarily schools. To some degree, developmental psychopathologists have looked at schools as settings for application of knowledge derived from basic research rather than as settings for such basic research. To the extent

that this remains the case, issues such as implementation will remain a chief impediment to the contribution of developmental psychopathology to education (and children's mental health) as well as the ways knowledge of development in schools can contribute to advancing developmental psychopathology. This stance calls for developmental psychopathologists to be closely involved in the next generation of school reform, the redesign of school settings, and the training of teachers (IES, 200a; Committee for Children, 2004). Penetration and cross-fertilization of education and developmental psychopathology, although compelling, advocated widely, and discussed thoroughly, is truly in the earliest stages of formation.

Assessing School Contexts in Developmental Research

Modeling the ways school experiences can add to, mediate, and moderate established trajectories of development and can formatively shape development in newly established domains (such as in peer or romantic relationships) allows for a more "sophisticated and comprehensive" understanding of development (Cicchetti & Aber, 1998). When it comes to studies of school-age outcomes (particularly in longitudinal follow-up studies), readers can refer to almost any recent issue of a developmentally oriented journal and find reports of fairly sophisticated modeling of school-age outcomes as a function of prior experience in home contexts or history of development prior to school (e.g., Brody, Kim, Murry, & Brown, 2004; Gutman, Sameroff, & Cole, 2003; Hill, Brooks-Gunn, & Waldfogel, 2003). However, it is rare for these reports to model experiences in school. Absent information on the school context and schooling processes, it is difficult to evaluate the legacy of early experience in light of the possibility that school experience mediates or moderates the effects of prior history or concurrent experience at home. Given the information available from short-term studies of school-age children that classroom processes contribute uniquely to school-age outcomes (e.g., Brody, Dorsey, Forehand, & Armistead, 2002; Howes et al., in press; NICHD ECCRN, 2004a, 2004b), not modeling such effects could lead to overestimating the linear, direct association between early experience (or early status) and later outcome.

When school experience is modeled in longitudinal follow-up studies, particularly those with information on child outcome or experience prior to school entry, results emerge that demonstrate both the power of schooling to moderate early experience (e.g., Christian, Bachnan, & Morrison, 2001; Howes et al., in press; Morrison & Connor, 2002) and the extent to which experiences in school add to

prior history (e.g., NICHD ECCRN, 2004b). Not surprisingly, the power of early development to establish stable trajectories (Gutman et al., 2003; Hill et al., 2003) is also evident in these studies in the legacy of early experience in determining later functioning (NICHD ECCRN, 2004b).

Although not widely available a decade ago, well-standardized and validated assessments of schooling exist for a range of constructs. Standardized observational methods for assessing elementary classroom environments have been developed as a consequence of their use in several large-sample studies (e.g., Christian et al., 2001; NICHD ECCRN, 2002c). These assessments capture teacher behaviors and aspects of classroom climate related to social and academic functioning of children at both a global level and in terms of discrete behaviors and classroom conditions. Child and teacher report measures of classroom climate, school climate, teacher behavior, teacher-child relationships, and quality of peer relations and peer climate all have been developed and are used quite widely and efficiently in many research programs focused on schooling (e.g., Battistich, Solomon, Watson, & Schaps, 1997; Brody et al., 2004; Pianta et al., 2003; Roeser et al., 2000; Wentzel, 2002). Integrating these methodologies, conceptually and functionally, into programs of longitudinal research on development is another step advancing interdisciplinarity and integration.

The Determinants of Informant-Based Metrics

Informant-based assessments of behavioral and mental health outcomes are the most widely used indicators in developmental psychopathology research and clinical practice. Yet, their results can be misinterpreted because of inattention to how such ratings reveal (unexamined) combinations of child, informant, and setting characteristics (Kraemer et al., 2003). Meta-analyses as well as individual studies regularly report the association between teacher and parent report (the most commonly used informants) to be low, in the range of .25 (see Achenbach, McConaughy, & Howell, 1987; Kraemer et al., 2003). Rates of children showing elevated profiles across both school and other contexts are very low, and lower than rates showing problems in one setting only (e.g., Konold, Hamre, & Pianta, 2003). Methodological work suggests that informants in different settings are better-suited for assessment of some constructs than others, with mothers contributing less informant-related variance to assessment of internalizing behavior and teacher reports of externalizing behavior less influenced by informant factors than mother reports (Konold & Pianta, 2004; Kraemer et al., 2003).

Informant differences in the reporting of children's problem behavior are not in dispute; the issue is how they are interpreted. From a purely psychometric perspective, this lack of correspondence can be considered a function of error on the part of informants in both settings and ratings that result in imperfect estimates of a child trait. Cross-informant inconsistencies might also be interpreted in light of one informant's being accorded gold standard status with regard to a particular characteristic, either on empirical grounds (Kraemer et al., 2003) or for theoretical reasons. Or, the lack of correspondence between informants' ratings could be interpreted to reflect the contextualized nature of the behavior being rated and bring into focus how contextual and informant characteristics shape these behaviors (NICHD ECCRN, 2004b) as well as the informants' perceptions of those behaviors (Konold & Pianta, 2004). Because of the exceptionally widespread use of informant ratings in developmental psychopathology research, it is critical that these three interpretive strategies be examined more systematically (Kraemer et al., 2003) because of the potential for misinterpretation of results.

Schools are particularly well-organized to address this issue because one informant (the teacher) can provide ratings for a fairly large number of children who are under his or her supervision and with whom he or she shares no genetic relation (addressing a confound in parent-child ratings). Nested-design studies can then be conducted in which variance in judgments of problem behavior can be attributed to teacher, child, and school characteristics (e.g., Bryant et al., 2003; Hamre, Mashburn, Downer, & Pianta, 2004), and the dynamics of these associations can be modeled over time, or careful modeling of informant, situation, and trait effects can be undertaken (Kraemer et al., 2003). When these studies also assess the range of beliefs, affects, and experiences of teachers that contribute to their judgments, a more sophisticated understanding of how informant ratings reflect combinations of child, rater, and setting attributes, absent genetic confounds, would result. As implied in Roeser, Eccles, and Sameroff (1998), assessing characteristics of *teachers* that contribute to their judgments about and behavior with children is a critical missing piece of understanding school process effects, knowledge of which could transform how implementation challenges are addressed and conceptualized in school-based mental health programs (Rones & Hoagwood, 2000). Because of the prominence of informant-based rating scales in developmental psychopathology (and ultimately in clinical practice), the need to address these issues is imperative.

Summary

In sum, developmental psychopathology and education science have many points of mutual interest for strategic exploitation and exploration. For developmental psychopathologists, challenges in understanding the mechanisms of and responses to clinical trial interventions, implementing mental health programs at scale, discovery of contextual effects and moderating influences on behavioral and mental health outcomes, disaggregation of genetic confounds in analyses of contextual effects, and a more sophisticated interpretation of informant-based outcome assessments can be at least partially accomplished through integrative research designs and conceptual models that openly include school contexts in full form. For educators, research on important questions about the relative weight of schooling and the home environment, the value-added quality of schooling, or policy-related concerns about program effectiveness and development can be greatly enhanced by developmentally informed studies.

MODELS AND CONCEPTS TO GUIDE INTEGRATION AND INTERDISCIPLINARITY

The challenges facing integrative linkages between developmental psychopathology and schooling have roots in the historical, conceptual, and political forces that shape how disciplines grow up in different traditions of inquiry and institutionalization. The end result of these forces is a contemporary situation in which a variety of phenomena that ought to be of common interest and encourage common dialogue and discussion among developmentalists and educators (such as those outlined in the previous section) are often viewed through different conceptual, analytic, and theoretical lenses. As noted by Sameroff (2000), these forces coalesce to form dichotomizations that obstruct interdisciplinarity and integrative science (Towne & Hilton, 2004).

Disciplinary and mission-related dichotomies are not unique to developmental psychology and education; these barriers impede scientific progress in a variety of disciplines (Sameroff, 2000). Recent years have witnessed these dichotomies yielding to metatheoretical principles of integration and interdisciplinarity. Developmental psychopathology is one of the best examples of the use of these principles to advance integrative science, exemplified in research programs linking biological and behavioral systems such as studies of gene-environment interactions (e.g.,

McGuire et al., 1999; Waldman et al., 1998), associations between hormonal and behavioral regulation (Quas, Murowchick, Bensadoun, & Boyce, 2002; Watamura, Donzella, Alwin, & Gunnar, 2003), and neurobiological function and psychopathology (Nelson & Bloom, 1997). In contrast, developmental psychopathologists' measurement, sampling, and analysis of developmentally salient parameters (particularly contextual features) in school settings lag behind parallel efforts related to biological processes. This condition limits understanding of the nature and course of variation in emotional and behavioral disturbance (Rutter & Silberg, 2002; Sameroff, 2000) in much the same way as nature-nurture dichotomization may have constrained understanding of biobehavioral processes in development.

Systems and Development in School Settings: Two Useful Principles

General systems theory has been the primary conceptual paradigm in human development for at least the past 2 decades (see Lerner, 1998; Sameroff, 1995, 2000) and is responsible, in part, for the integration of behavioral and biological science noted earlier. Although the living systems perspective is foundational to developmental psychopathology, it has not yet penetrated educational research in anywhere near as complete a manner (for discussion of this issue, see Good & Weinstein, 1986; Pianta, 1999; Roeser et al., 2000). Dynamic, living systems models, operationalized through developmentally informed research in school settings (e.g., Lyon, 2002; Pianta, 1999; Roeser et al., 1998), are by far the exception in education science, which tends to be dominated by econometrics (Grissmer, Flanagan, Kawata, & Williamson, 2000; Rivkin, Hanushek, & Kain, 2000; Towne & Hilton, 2004), in which developmental and interactive processes are not modeled, and qualitative ethnographic approaches in which population estimates are eschewed in the pursuit of process description. One of the values of developmentally informed concepts, design, and analysis for education is a methodological and conceptual framework that integrates large-scale quantitative analysis of structure-outcome associations with attention to mechanisms and processes (e.g., NICHD ECCRN, 2002c; Towne & Hilton, 2004), an approach reflected in new funding initiatives related to school readiness interventions (Bryant et al., 2003) and clinical trial research in teachers' professional development (IES, 2004a).

Two principles of systems theory are particularly germane to bridging school effects and school adaptation with developmental psychopathology. These principles—holis-

tic units of analysis and multilevel co-action—are evident in work on schooling focusing on relationships between teachers and children (Birch & Ladd, 1997; Hamre & Pianta, 2001; Ladd & Burgess, 1999), early intervention with high-risk preschoolers (e.g., C. T. Ramey & Ramey, 1998), school-based research and interventions with children at risk for aggressive/disruptive behavior problems (Boyle et al., 1999; Catalano et al., 2003; Greenberg et al., 2001; Jalongo et al., 1999; Walker, Stiller, Severson, Feil, & Golly, 1998), and work focusing on developmental change as a function of transitions into elementary school (Brody et al., 2002, 2004; Pianta & Cox, 1999), middle school (Roeser et al., 1998, 2000), and high school (Felner, Favazza, Shim, & Brand, 2001).

Holistic Units of Analysis

A central issue in the study of school effects and in understanding patterns of adaptation in schools is selection of the appropriate unit of analysis. Lerner (1998) emphasizes that the causes of development are *relationships* among systems and their components, not actions in isolation. With regard to schooling, a focus on relations and interactions can take two forms, one in which the goal is to understand school effects on development in a particular domain, and another for understanding patterns of adaptive and maladaptive functioning across domains.

With regard to schooling effects, a relational unit is consistent with the perspective advanced by Bronfenbrenner and Morris (1998) when they argue that the primary engine of development is proximal process—interactions that take place between the child and context(s) over extended periods of time. There are several examples of research programs that focus on relational, holistic units of analysis in schools, and the yield of these research programs for understanding the role of proximal process for both social and cognitive/achievement development has been substantial.

As one comprehensive example of a focus on relational units, Noam and Hermann's (2002) school-based prevention approach emphasizes the primary importance of a relational unit as a focus of intervention and of evaluation (Noam et al., 2001). This intervention aims to establish for each child a multifunction relationship with a "coach/mentor," based explicitly on the rationale that such relationships function as resources and resilience mechanisms in counteracting the effects of risk mechanisms. Furthermore, in their assessment of the implementation and effects of these ideas in classrooms, Noam and colleagues' work also assesses process and outcome at the relational level. Thus, the success of the intervention is not only measured in terms of academic achievement tests or problem behaviors

but in terms of the child's use of the interventionist and qualities of the child's interactions with other relational and informational resources in the school. The results of this work corroborate the idea that both school adaptation and school effects can be understood, assessed, and altered through a focus on relational processes and units.

As an example of the distinction between relational and decontextualized units of analysis, Hamre and Pianta (2001) examined teachers' perceptions of their relationships with children in kindergarten and the consequences of these perceptions for understanding and predicting disciplinary infractions in the school setting. It was hypothesized that teachers' perceptions of their relationships with children provided a more accurate and context-sensitive indicator of, on the one hand, the competence of the child in the classroom setting and, on the other, the affordance value of that setting reflected in the teachers' feelings about the child. When examining prediction from teacher-child relationships, Hamre and Pianta adjusted for these same teachers' ratings of the child's disruptive problem behavior and verbal ability, both decontextualized indicators of competence. Hamre and Pianta reported that when predicting achievement as well as disciplinary infractions at school some years later, kindergarten teachers' perceptions of relational negativity, not their ratings of problem behavior or verbal IQ, were by far the strongest predictor.

In this way, conceptualization of school adaptation in context-specific, relational terms appeared to tap processes more salient for predicting future functioning (in similar settings) than did a less contextualized assessment. One might make the same argument, in the area of peer relations and social development, for the value of sociometric procedures, in the sense that indices of popularity or rejection capture relational-level functioning in a specific context (social networks) and in so doing advance understanding and prediction of function in that setting in ways that decontextualized assessment of traits or behaviors does not (Gifford-Smith & Brownell, 2003).

The gain to be had from a focus on relational processes and units is not limited solely to social processes or social problems. Understanding academic success is also improved when conceptualizing the phenomena at the relational level. For example, in the education research literature, academic growth is more successfully modeled and predicted when information is available on the qualities and quantity of the child's attention to and engagement with specific forms of instruction that map onto their prior learning history rather than simply their exposure to instruction. Thus, it is not enough to know the child is receiving a certain amount or type of instruction that predicts, for

example, growth in literacy over the first-grade year; it is the child's *engagement* in learning activities that map onto prerequisite skills (Christian et al., 2001; Morrison & Connor, 2002).

In younger children, it has been shown that the value of instructional interactions can be reflected by the ways emotions, perceptions, and motivational processes activate and shape children's help-seeking behavior (Nelson-Le Gall & Resnick, 1998; Newman, 2000). In middle schoolers, it has been amply demonstrated that achievement growth is conditioned on an assortment of motivational and emotional factors that *interact* with what is offered in the classroom (Roeser et al., 1998). More specifically, for children in which normative developmental trends lead them to value autonomy, exploration, and a sense of identity, control-oriented discipline and competitive academic values tend to produce lower levels of motivation and achievement and higher levels of problem behavior in large part because of the mismatch between context and developmental forces—a relational, interactive mechanism. Thus, instruction, or stimulation, is something more than simply demonstration, modeling, and reinforcement assessed as inputs from a teacher, but is instead a complex, socially and psychologically mediated, bidirectional process, the understanding of which can be improved through developmental science (IES, 2004a; Towne & Hilton, 2004). From a somewhat different perspective, the effective dose of schooling inputs is not accurately characterized by program-level parameters such as time allotted to instruction, curriculum, or the type of program or intervention, but is reflected in the actual engagement of the child in the ingredients of these inputs, confirmation of the importance of implementation parameters (Greenberg et al., 2001; IES, 2004a).

It is also appropriate to discuss relational or holistic units when focusing on the various domains of development that intersect with experiences in school. Particularly in educational research, motor, cognitive, social, and emotional development are often treated as independent entities on parallel paths, influenced by practice in that specific domain, such as in studies linking the amount and quality of instruction in literacy with literacy performance (Morrison & Connor, 2002). Yet, when cross-domain associations are examined, they are not infrequently detected, such as when the level and nature of instruction a child receives in school affects emotional health assessed by mothers (NICHD ECCRN, 2004b). Because educational practice is so often designed to influence domains in isolation (e.g., phonological processing, mathematics computation, on-task behavior), it is easy for education science to

reinforce the notion that developmental domains are best considered as separate units of adaptation and functioning rather than facets of integrated, global patterns of adaptation to broad developmental themes (Gambone et al., 2002; Sroufe & Rutter, 1984).

Because domains of development and subsystems of behavioral competencies are interconnected in more holistic organizations, a single educational practice can trigger or stimulate multiple domains, such as when instructional practice activates motivational and cognitive processes (Roeser et al., 1998). Therefore, conceptualizing, assessing, and documenting transactional influences of educational practices across multiple domains of functioning could be a key focus of cooperation between education and developmental scientists. Cross-domain overlap is so strong that Roeser et al. emphasize the need for “cataloguing the features of academic environments that impact, either positively or negatively, on both academic and emotional outcomes simultaneously” (p. 170). Because cross-domain linkage (or asymmetry) is somewhat familiar to developmental scientists (Steinberg & Morris, 2001), this is one area in which a developmental psychopathology perspective can advance educational research. Developmental psychopathologists interested in understanding schooling in relation to mental health and socioemotional adaptation may wish to focus attention as well on how functioning in these domains varies with academic skill and instructional experiences as much as with peer relations and social systems in the school.

Multilevel Co-Action

Schools are multilevel systems, and relational processes are evident both within and across levels. For developmentalists interested in multilevel interactions and transactions (e.g., Gottlieb & Halpern, 2002; Sameroff, 1995), schools can be a rich source of evidence. For example, although there is considerable evidence that child-teacher relationships alter trajectories of development in social and academic domains (see Pianta et al., 2003, for a review), it is also the case that the nature and qualities of child-teacher interactions and relationships and their effects on development are moderated by class size (NICHD ECCRN, 2004a), teacher mood and depression (Hamre & Pianta, 2004), and the nature and organization of schools (Battistich, Watson, Solomon, Lewis, & Schaps, 1999; Felner et al., 2001).

Similarly, multilevel, multisystem interactions are evident when school and school district policies about the age/grade of transition to secondary schools interact with school climate, procedures around accountabil-

ity and discipline, and students' prior experience and attitudes and expectations to affect their performance in the new school (Eccles, Early, Fraser, Belansky, & McCarthy, 1997; Gambone et al., 2002). Multilevel co-action (Gottlieb & Halpern, 2002) is also apparent in the interaction between policies concerning age of entry to school and the nature and quality of instruction that children receive in specific domains (Morrison & Connor, 2002; Stipek, 2002). From a less process-focused perspective, multilevel interactions are evident in the class of education policy studies focused on the association between policy parameters (class size, finance, teacher credentialing) and child achievement outcomes (Grissmer et al., 2000; Rivkin et al., 2000). It is routine in investigations of these issues, often using large survey data sets, that unique variance is attributed to each of many levels—state, district, school, classroom/teacher, and peers (Rivkin et al., 2000)—although moderating and mediating proximal processes and mechanisms are not often modeled in such studies.

These two principles of general systems theory—holistic units of analysis and multilevel co-action—inform a body of work on “developmental interactionism” (Magnusson & Stattin, 1998) that focuses attention on issues of goodness of fit, relationships, mediation and moderation of effects, and related relational constructs (Boyce et al., 1998). These principles advance a more sophisticated and comprehensive (Cicchetti & Aber, 1998) picture of the dynamics and motivation of behavioral change and adaptation than do the traditional maturationist, stage theory, or behavioral conditioning paradigms typically used in education science (Good & Weinstein, 1986). These traditional theoretical paradigms stand as both obstacles to and opportunities for interdisciplinarity when developmental psychopathologists enter into and focus on education settings (Eccles, Wigfield, & Schiefele, 1998; Pianta, 1999).

Integrative, Interdisciplinary Models

The models used by investigators to approach research questions related to schooling and developmental psychopathology play a critical role in shaping findings and ultimately theory. Current conceptualizations tend to be limiting with regard to how they approach research in relation to educational practice and in terms of cross-disciplinary efforts within research programs focused on schooling and development. Moving beyond the limits imposed will require different conceptual frameworks that are more integrative and comprehensive.

Moving beyond Research/Practice Dichotomies

As noted earlier, one of the more serious conceptual impediments to a fuller realization of the mutual benefits of interdisciplinarity in education and developmental science is the tendency toward dichotomization within and across these disciplines (Sameroff, 2000). The research/practice polarity is by far the dichotomy through which developmental psychopathology and education have been most often linked and kept apart. Research/practice linkages between developmental research and education are typically centered on instruction and academic learning and only recently have focused on social interactions, peer relations, problem behavior, and psychopathology (e.g., Elias, Zins, Graczyk, & Weissberg, 2003; Evertson & Weinstein, in press; Gifford-Smith & Brownell, 2003; Greenberg et al., 2001; Hoagwood & Johnson, 2003; Weissberg & Greenberg, 1998) and are most often reflected in discussions of intervention implementation and fidelity.

The dichotomy of the research/practice framework is embodied in two of Renninger's (1998, p. 212) assumptions about schools and development:

1. If more educators (teachers, teacher educators, administrators, policymakers, parents, etc.) were knowledgeable about developmental theory and research, and had tools to think about classroom decision making that were informed by what is known about how students learn, research in developmental psychology would radically change the mainstream of educational practice.
2. If more researchers were knowledgeable about educational practice—the strengths and needs of teachers and their working about students, and invested time working with educators to consider the implications and directions of their research efforts, research could contribute more directly to practice.

From one point of view, these two assumptions advance the goal of integration and counter the dichotomization of developmental research on the one hand and educational practice on the other. Yet, at the risk of making an oversimplified interpretation, these assumptions could also lead to viewing theory and research as the province of developmental psychology and practice as isomorphic with education—what goes on in schools to change developmental outcomes.

The regular, naturalistic, instructional and social interactions among children and between children and teachers in a school setting (Pianta, 1999; Roeser et al., 1998) are no more “applied” or reflective of “practices” and therefore the province of education than are interactions between children and their mother (Sroufe, 1996) or between peers

(Gifford-Smith & Brownell, 2003). In fact, viewing interactions in school settings as the proper focus of education, and the programmatic, standardized interactions that take place in intervention trials as the focus of developmental psychopathology, is one reason implementation is such a challenge to prevention/intervention research (e.g., Greenberg et al., 2001; Rones & Hoagwood, 2000). This research/practice dichotomy will continue to plague efforts to extend developmental science unless it is resolved.

That child-teacher interactions have an explicitly directed, intentional component should make them even more interesting as a focus of developmentally oriented research (IES, 2004b; Morrison & Connor, 2002; Roeser et al., 1998; Rutter & Maughan, 2002). It would seem that the agents of such interactions (e.g., teachers) would be as interesting a focus as the agents of mother-child or peer interactions (Pianta et al., 2003). As an example of work attempting to understand the parameters regulating teachers' behavior under natural conditions, Hamre and Pianta (2004) recently demonstrated that teachers' self-reported depressive symptoms predicted their harsh and withdrawn behavior toward children, and teachers' sensitive behavior was predicted by both their representations of relationships with children (Stuhlman & Pianta, 2001) and their experiences of unresolved loss (Zeller & Pianta, 2004). Further extension of this line of thinking could lead to research on the development of individuals who assume roles as educators (teachers, principals), particularly the experiential, attitudinal, and training-related mechanisms that shape their behaviors with and decisions about children over time (Rimm-Kaufman, Storm, Sawyer, Pianta, & La Paro, 2004). The science of human interaction and behavioral development, and the conceptual paradigms and methods it uses, are directly applicable to the interactions in school settings that contribute to the behavior and development of children and adults.

From a contextualist framework, schools, like families, are social and physical settings in which processes of social interaction, teaching, and engagement in activity contribute to individual (and group) patterns of growth, change, and adaptation. *Integrative* contextualism builds on the general contextualist framework (Cicchetti & Aber, 1998) by explicitly directing attention not only at features of the context but also at those aspects of developmental process that *cut across* context and give meaning to experience. When viewing schools from this perspective, overarching questions about mechanisms and processes in development can be examined using many of the same conceptual and methodological insights that have been applied (and acquired) in the study of development in other settings, such as families and child care environments.

The integrative contextualist framework depicted in Figure 13.1 is entirely consistent with the type of multilevel model of development in context that is a well-accepted feature of developmental psychopathology (Bronfenbrenner & Morris, 1998; Cicchetti & Dawson, 2002; Sameroff, 1995, 2000). In the conceptualization of developmental ecologies shown in Figure 13.1, school effects and school adaptation are fully integrated within the range of contexts that shape development, similar to what is posited in most ecological models. However, this integrative model differs from most depictions of ecological frameworks in at least one important respect. The different forms of process or activity (structural, proximal, self-regulatory, biobehavioral) that influence or form the basis of outcome trajectories are explicitly threaded through settings in such a way that process is continuous across settings rather than bounded by settings.

This emphasis on continuity of processes *across* settings, in contrast to process as *bounded within* settings, opens up ways to examine and test aspects of the general ecological-developmental model in schools as the settings of interest. For example, in generalized form, structural features of settings often operate as regulators of proximal process. In the same way that in family-focused research one might examine income or family size or parents' educational level as resource dimensions affecting parental sensitivity, in schools one might focus on per pupil expenditure, school size, or teachers' certification or experience levels as they relate directly and indirectly to child outcomes and to proximal process mechanisms such as the quality of instruction (e.g., NICHD ECCRN, 2004a). At the proximal process level, in research focused on family adaptation or family effects, child-parent relationships and interactions, parents' psychological attributes and development, sibling relationships, and peer relationships are modeled as part of the ecology. In school settings, proximal processes related to teacher-child relationships and interactions, classroom social and instructional qualities, collaborative grouping of peers, and peer sociometric status are also proximal agents of change that likely involve many of the same mechanisms as the corresponding family-based proximal processes (e.g., Gambone et al., 2002), but they have yet to be examined with this cross-validation of general principles in mind.

To elaborate, instead of positing that relational mechanisms and processes that occur between parents and children in home settings are separate or somehow different from relational processes that may be activated toward adults in child care or school settings, the model in Figure 13.1 posits that relational processes are activated and de-

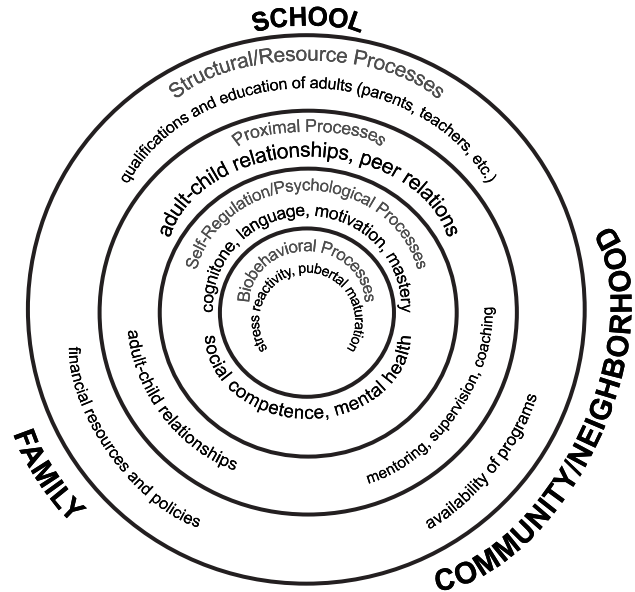

Figure 13.1 Integration of selected developmental ecologies.

velopmentally meaningful across ecologies. Adopting this perspective could lead to research on the conditions for activation, the nature, quality, and intensity of attachment experiences with adults across settings, or the developmental antecedents and consequences of various patterns of relational experience with adults in different settings (e.g., Stuhlman, 2003), that in turn could inform discussions about the relative uniqueness of experience with specific adults or the possibility of compensatory processes (O'Connor, 2003). In one such study (Stuhlman, 2003), cluster analytic approaches applied to adult-child relationship observations conducted in child care and family settings revealed that person-focused descriptions that integrated experience across child care and home settings were more robust predictors of later outcomes than setting-specific indicators modeled additively.

To continue, the processes by which self-regulation mechanisms develop and function have been widely studied in relation to family effects and patterns of adaptation in family settings. These mechanisms, involving linkages of cognitive, relational, motivational, emotional, and social processes, have been mostly examined in relation to family effects with behavioral adaptation in schools typically functioning as outcome indicators in follow-up studies. Similarly, normative biobehavioral processes related to temperament, stress reactivity, and pubertal development have received considerable attention related to developmental antecedents and sequelae in family settings. But biobehavioral development and self-regulatory processes

are also relevant to understanding school adaptation and school effects (Quas et al., 2002; Watamura et al., 2003). For example, cortisol levels vary with prior experience in families (Quas et al., 2002) but also appear related to experiences during the school (or child care) day (Watamura et al., 2003) and interact with the peer network and quality of the child-teacher relationship in classroom settings (Little & Kobak, in press). In an elegant example of cross-context integration at the process level, Little and Kobak examined cortisol secretion of students as a function of the quality of their relationship with the teacher in special education classrooms for children with emotional disturbances. High levels of secretion were evident for these students, on average, indicating the stressful nature of the setting. However, the students sharing a close, emotionally supportive relationship with the teacher showed significantly lower levels of cortisol than did their classmates. In this study, adult-child relationship quality and biobehavioral regulation were examined not in family environments but in classroom settings, and results revealed mechanisms nearly identical to those revealed by research done in family settings.

Moving beyond Disciplinary Boundaries

Examples of interdisciplinarity involving developmental psychopathology and education are manifest in interagency research initiatives related to school readiness and early literacy (e.g., Lyon, 2002), teacher professional development (IES, 2004a), the recent integrative focus on positive youth development and transitions from middle childhood to high school (Eccles & Gootman, 2002; Gambone et al., 2002), research on juvenile offenders and psychopathology (Gottfredson, 2001), and research training initiatives (Towne & Hilton, 2004) that include schools and schooling as a central, not peripheral, focus.

Perhaps one of the best examples of the value of interdisciplinarity for the generation of new knowledge is the area of early literacy described in Lyon's (2002) summary of 2 decades of basic research on language development, phonological processes, cognitive and neurological mechanisms, instructional processes, and learning to read. The recent report by the National Reading Panel (NRP, 2000), in which consensus recommendations could be made concerning the value, importance, and even necessity of direct exposure of children to phonological-level information in written language, could not have been made without the focus of multiple research traditions, from a variety of disciplines, reflected in Lyon's analysis. In short, real progress on identifying basic developmental mechanisms in early literacy and the contextual conditions that activate,

stimulate, and foster growth in those mechanisms has occurred, largely as a function of efforts that crossed disciplines. Interestingly, the challenge for the next decade in literacy initiatives is how to support and ensure children's exposure to experiences at home and in schools that foster these processes, illustrating the importance of examining basic processes across multiple contexts, as in Figure 13.1. On the other hand, it continues to remain the case that even context-sensitive research, for example on delinquency (e.g., Scaramella, Conger, Spoth, & Simons, 2002), may not fully capture how schools influence peer-related experiences of at-risk youth by the way they group children or respond to individual differences.

Notable among studies that do achieve some measure of integration across several ecological levels and psychological processes is the NICHD Study of Early Child Care and Youth Development, which has followed a design strategy from inception of careful process-based assessments of key developmental settings and outcomes across multiple domains (NICHD ECCRN, 2001, 2002b, 2003). Originally designed as a careful and thorough examination of effects of child care on development, this study strategically captured structural and process dimensions of the home and child care settings to which the children were exposed in an effort to differentiate associations with developmental function and growth. As the more than 1,000 children enrolled in this prospective study moved on to school, developmentally sensitive observations of classroom settings in first, third, and fifth grades as well as child, peer, teacher, and principal report of the structural and proximal process qualities of the school environment and detailed assessments of child adjustment across multiple domains within that environment exemplified a fairly thorough integrative approach to contextualism. As ecologies of development expand as the participants move to high school, the study's focus includes experience in community activities, employment, and school and out-of-school settings as well as in families (NICHD ECCRN, 2003, 2004a).

A number of other integrative longitudinal studies have followed children from infancy into school or enrolled samples at the start of school and have included assessment of the school setting as part of their protocols (e.g., Alexander & Entwisle, 1988; Conduct Problems Prevention Research Group [CPPRG], 1999, 2002; Hill et al., 2003; Kellam, Ling, Merisca, Brown, & Ialongo, 1998; Morrison & Connor, 2002; C. T. Ramey et al., 2000; Sroufe, Carlson, Levy, & Egeland, 1999; Vitaro, Brendgen, Pagani, Tremblay, & McDuff, 1999) or at the onset of key developmental or school transitions (e.g., Eccles, Lord, & Roeser, 1996). Two very broad trends are suggested by this literature.

First, from the perspective of assessment and conceptualization, as the value of school settings is more completely assessed, particularly at the level of proximal process, a more complete picture of development in context emerges. Rather than models of linear effects of early experience, complex models emerge that describe how mechanisms of continuity and stability interact with stimulation and variation in experience (e.g., Sroufe et al., 1999; Steinberg & Morris, 2001; Vitaro et al., 1999). In these models, the school setting is an important (and underresearched) source of this variation (Morrison & Connor, 2002; Rutter & Maughan, 2002; Stevenson & Lee, 1990; Towne & Hilton, 2004; Vitaro et al., 1999). Second, when examining the broad, longitudinal patterns revealed by this work, particularly when including studies of development since birth, school effects appear fairly weak relative to home effects in early elementary school. But as the actions of peer networks, pubertal development, and increasing autonomy and selfhood emerge and interact with differentiating school contexts, the child becomes a critical active agent in determining the nature and value of school-related experience (Roeser et al., 1998; Steinberg & Morris, 2001). Learning more about how opportunity structures and assets in schools interact with self-determination remains an important goal for interdisciplinary collaborations. To accomplish such collaborations, conceptual models, research designs, and assessment protocols are needed to enable investigators to strategically sample school environments and adaptation with the same sophistication as they approach peer or family settings.

MULTILEVEL TRANSACTIONAL PROCESSES AND SCHOOL ADAPTATION

One reason for Rutter and Maughan's (2002) conclusions regarding the lack of progress in understanding school effects and school adaptation is that schools are complex—in many ways, more complex than families, or perhaps even child care settings. They involve levels of analysis that challenge conceptual and analytic models; the school setting changes year to year, month to month, day to day, and often within days; and the potential social influences (peers, teachers, other adults), instructional influences (teaching styles, curriculum, subject matter), and opportunities available to children can shift rapidly and be very hard to track and model. This complexity offers opportunity (as discussed earlier) as well as obstacles to developmental psychopathologists. In this section, attention turns to describing and mapping school settings as they intersect with development and presenting in more detail those aspects of

school settings that may be of most interest to developmental psychopathologists.

Schools: Dynamic, Multilevel Settings for Development

Eccles and Roeser (1998) apply the general ecological model to the study of development in school settings and posit nested layers related to (1) district policy and resource; (2) school-level climate, policy, and practices; (3) classroom environment, including instruction and attributes of teachers and peers; and (4) child-level factors related to motivation, ability, and socioemotional characteristics. Within these levels, Eccles and Roeser discuss the variety of specific agents that interact with one another to affect child outcomes. In particular, they attend to the dynamic interactions that take place within and across layers. Additional ideas about the study of school contexts come from Boyce et al. (1998), who present five propositions about context using a definition of context as inherently bidirectional and meaning-based. Boyce et al. emphasize the need to attend to the dynamic changes that take place in settings across time and the additive/mediated/moderated influences that features of these settings have on development. The consensus picture that emerges from these models is of school (and other settings) as dynamic, multidimensional, multilayered systems, the effects of which on development cannot be understood or modeled in simple linear, additive fashion. These broad principles are outlined next.

Schools Are Multilayered Settings

It is widely recognized that school settings reflect several layers of structural and process features that reciprocally interact to affect child outcomes and adaptation. School policies and practices are highly regulated by states (Berliner & Biddle, 1995) and in turn influence school-level structure, organization (e.g., Felner et al., 2001), and climate (Battistich et al., 1999). These more proximal processes affect and are affected by classroom-level processes such as peer networks or teacher beliefs (Brophy, 1998; Evertson & Weinstein, in press). At the same time, it is well-known through intervention research that attempts to alter classroom processes such as management or instruction are constrained by district- or school-level factors such as funding, staff resources, and even the physical facilities (Darling-Hammond, 1997; Fashola & Slavin, 1997; Felner et al., 2001). Likewise, children's achievement motivation, a child-level factor, is influenced by qualities of the classroom, such as instruction, and this association is further moderated by school-level beliefs and practices about competition, con-

trol, and support (e.g., Eccles et al., 1996, 1997; Roeser et al., 2000).

Boyce et al. (1998) discuss the difference between structural and functional aspects of contexts and identify the need to attend to interactions among structural and functional, or process, features. Although the association between structure and process has been a focus of developmentalists' research on family and child care contexts (NICHD ECCRN, 2002c), there are fewer developmentally informed studies of the associations between structural variables such as pupil-teacher ratio and process features such as instructional interactions and student engagement (Eccles & Roeser, 1998; NICHD ECCRN, 2002a, 2002b, 2002c). However, when classroom process has been observed in developmentally oriented studies, classroom interaction, student engagement, and social and academic outcomes have been shown to differ as a function of structural features such as pupil-teacher ratio (Blatchford, Goldstein, Martin, & Browne, 2002; Blatchford, Moriarty, Edmonds, & Martin, 2002; NICHD ECCRN, 2004a), but the associations are complex (discussed later).

In an elegant example of demonstrating the distinction between classroom and individual levels of experience in schools, Kellam et al. (1998) demonstrated that the positive effects of a first-grade preventive intervention on subsequent aggressive behavior in middle school was moderated by the level of overall aggressive behavior among children in the first-grade classroom. Thus, the long-term effects of this intervention on individual first graders were in part conditioned by factors at the classroom level. These illustrations from the class size and prevention literatures confirm the widespread agreement that school effects and schooling processes are best understood in studies using a multilayered systems model that emphasizes the possibilities for moderation and nested effects (Howes et al., in press).

School Settings Are Multidimensional

A central issue in studies of proximal process effects on development is the specificity of effects. To use a more familiar example, can the effects of mother-child relationships on development be attributed largely to the effects of a global dimension of mothering such as sensitivity on a broad range of outcomes, including cognitive and emotional functioning (see NICHD ECCRN, 2002a), or are there more differentiated links between specific aspects of mothering (such as emotional warmth) and specific child outcomes (such as positive mood)? The same issue is present in the study of proximal processes in child care settings, when global quality is the focus, and in schools, particu-

larly in relation to classroom climate and whether effects are best detected through global indicators or specific features of the setting (e.g., Morrison & Connor, 2002).

In a recent example of the multidimensionality of school settings, two dimensions consistently emerge from factor analysis of classroom observations: instructional support and emotional support (NICHD ECCRN, 2002c; Pianta & La Paro, 2003; Pianta, La Paro, Payne, Cox, & Bradley, 2002). More important, it has been shown that these two dimensions to some extent predict differentially children's social and academic outcomes. For example, when evaluated in the same prediction model, instructional support for learning predicts achievement outcomes to a significantly greater degree than emotional support predicts the same outcomes (Howes et al., in press). Alternatively, children's anxious behavior reported by mothers is predicted by the degree of structure and pressure in the classroom setting (NICHD ECCRN, 2004b) and higher levels of emotional support predict a very broad range of competencies, mostly social (Howes et al., in press). In fact, Morrison and Connor (2002) argue that the effects of schooling on development have to be modeled at the level of specific forms of input and resource that are matched to specific child abilities and skills. Thus, according to Morrison and Connor, it is not only necessary to conceptualize and measure the classroom setting (or school) in terms of specific aspects of the instructional or social environment, but also to gauge the effects of those experiences relative to how well they match the child's capacities and skill. In this view, school effects are predominantly in the form of interactions between specific inputs from the classroom and specific skills of the child. Morrison and Connor suggest that one reason for the lack of detected school effects in the literature (Rutter & Maughan, 2002) is that such effects have been estimated by global assessments and global conceptualizations of the potential inputs in the classroom setting rather than through designs and theories focused on specific features of settings.

School Settings Are Dynamic

A key aspect of the Boyce et al. (1998) conceptualization of contexts is their attention to the *dynamics* of how contexts change over time in the nature and quality of their effects on development. Boyce et al. emphasize that contexts broaden, deepen, differentiate, and become more specific in effects over time. *Differentiation* of the school context is seen in the increased subject matter compartmentalization of programming from elementary to middle to high school; the increasing number of teachers and other adults that interact with and are responsible for teaching children as they move

through the school years; and the complex differentiation of the ways schools regulate peer interactions, interests, and competencies as children move to advanced grades in the form of interest-specific clubs, athletic programs, and leadership opportunities. As the child's experiences in school are increasingly driven by the match between the child's interests and motivations and the quality and availability of such opportunities, the effect of schooling *deepens and individualizes*. Particularly as the child becomes an increasingly active agent in seeking and drawing value from these experiences (Boyce et al., 1998), the salience of school as a setting increases. Thus, we see reports from national surveys in which high school youth describe school as a setting in which valuable relationships with adults occur, but that the nature of these relationships differs as a function of the pattern of the child's involvement in school—in one case a coach, in another a club advisor, in another a school counselor (see Gambone et al., 2002).

Pianta et al. (2003) drew a conclusion consistent with this view of the school setting as dynamic in terms of teacher-student relationships. In this review of the literature on relationships from kindergarten through 12th grade, it was apparent that through the elementary school years, the child was a far less active agent in establishing and determining the effects of relationships, with main effects of teacher-reported relationship quality the predominant form of association with child outcomes. As children entered middle school, this pattern changed considerably; the nature and quality of child-teacher relationships was far more a function of the child's (or teacher's) efforts to actively select and maintain these relationships based on mutual goals and understandings, and the effects of child-teacher relationships were increasingly evident when risk factors were active—a developmental shift from mildly promotive to more active protective influence (Rutter, 1987).

Schools Are Affected by External Demands and Macroregulations

As is also the case with the Eccles and Roeser (1998) model, Boyce et al. (1998) emphasize that contextual parameters that regulate individual development (and group behavior) also shift in response to external demands, what Sameroff (1995, 2000) would argue are macroregulations. An assortment of macroregulations regularly take place in schooling, and as has been discussed (Berliner & Biddle, 1995; NCES, 2003), the existence of such shifts in policy or practice in school settings afford developmentalists numerous opportunities to examine questions concerning transactional influences.

Aspects of schooling in which considerable macroregulation is evident are the increasing dominance of academic standards assessment (Berliner & Biddle, 1995; NCES, 2003) and discipline policies of zero tolerance for weapons and illegal substances (Noam et al., 2001). In both of these shifts, school settings have defined what is adaptive and maladaptive in relation to children's academic functioning and behavior, and a prescribed set of procedures have been put in place for schools to use in responding to children who deviate from expectations. These regulations have had profound effects on the nature of children's school experiences. In addition, policy shifts in relation to class size, student assessment, legal age for dropping out of school, retention, and requirements for experiences like summer school and tutoring have all been altered in a variety of states in response to the federal- and state-mandated attention to accountability. In nearly all these instances, policy shifts have in turn had repercussions (mostly unexamined) for process-level shifts in classrooms and schools that transform the nature of children's experiences in those settings.

For example, although 10 years ago few, if any, states (or school divisions) articulated specific performance standards for children at any grades, for the high school class of 2005 in Virginia and an assortment of other states, graduation will be determined by whether the youth passes a series of standardized tests (see Berliner & Biddle, 1995, for an extensive discussion of high-stakes testing). In New York, the Regents' examination, which was at one time a feature of college-track students' careers, is now required of all graduating seniors. The macroregulatory effects of the accountability movement has had effects on schooling experiences that extend into prekindergarten years: changes such as reductions in recess and lunch periods, increased usage of basic skills curricula and teaching methods, increased stress reported among teachers and teacher turnover, and introduction of state laws and regulations lowering the age at which children can legally drop out of school (Berliner, 2004). For the most part, these effects have been documented in the media and qualitative accounts and have received much less attention in developmental research despite the opportunity they present for studying multilayered effects of regulation on development.

One could easily recognize in these macroregulations numerous opportunities to examine variations in school experience (e.g., changes in dropout ages; shifts in the availability of unstructured time with peers in school) consistent with developmental psychopathology's interests in

factors that alter the trajectory of individual and group patterns of adaptation. To the extent, for example, that unstructured time with peers is a context for negotiating and practicing positions in the social network, or the formation of cliques or crowds (Gifford-Smith & Brownell, 2003; Steinberg & Morris, 2001), elimination of such opportunities places a constraint on this developmental phenomenon. Likewise, to the extent that school is a context supporting resilience processes (Felner et al., 2001; Noam & Hermann, 2002; Noam et al., 2001; Pianta, 1999; Roeser et al., 2000), easing dropout requirements potentially undermines these processes and their effects, but such effects may also be moderated by the child's goals and skills. By reflecting the multilayered nesting of processes that regularly vary within or across school settings, developmentally informed research designs allow for evaluation of the dynamics of contextual effects that can be difficult to model in settings that are less exposed to such shifts.

Effects of School Settings Are Meaning-Based

Boyce and colleagues (1998) emphasize that attempts to model the effects of a setting on development must acknowledge the meaning of that setting for the individual child. This highly individualized conceptualization of developmental "value" for experience is consistent with the focus on relational units of analysis derived from systems theory that was discussed earlier. The implication of conditioning the value of experience in a setting on the child's developmental *needs* is that to understand, for example, the effects of schools, one must have a theory of development that posits the developmental needs of the child vis-à-vis the school setting (Connell & Wellborn, 1991). In their review of whole-school restructuring projects and their consequences for student mental health, Felner et al. (2001, p. 3) concluded that often there is a "mismatch between the conditions and practices students encounter in grades K through 12 and the developmental needs, readiness, and capacities of students."

More than a decade ago, Connell and Wellborn (1991) advanced a theory in which three basic developmental needs are posited (competence, autonomy, and relatedness) and an approach in which schools' response to those needs can be assessed through child and teacher reports. This work has been extended in numerous ways, most recently in a National Academies of Science report on youth development (Eccles & Gootman, 2002), and summarized in the Gambone et al. (2002) integration. Common across all the conceptualizations is a focus on the child's emotional and social needs for connection and relationships

(to persons, goals, and institutions or groups), a need for safety and a structured physical environment, the need for competence and meaningfully challenging opportunities for building skills, and the need for linkage and integration among settings and experiences. Connell, Aber, and Walker (1995) conceptualize these needs in terms of productivity, connectedness, and a capacity to navigate and explore.

Paralleling the articulation of developmental needs and outcomes has been a focus on what contexts do to respond to those needs and enhance positive outcomes. Again summarizing across diverse efforts, Gambone et al. (2002) identify, in addition to basic shelter and health, four mechanisms of support and opportunity: (1) supportive relationships with adults and peers, (2) opportunities for meaningful involvement and membership, (3) challenging and engaging activities and learning experiences, and (4) safety. Rarely have schools been the focus of assays of these supports and opportunities, whether in individual community settings or at state levels. Yet classroom process research has identified instructional support and emotional support as dimensions of experience related to gains in functioning for elementary school children (Howes et al., in press; NICHD ECCRN, 2004b; Pianta et al., 2002), and the literature on middle and high schools has been largely responsible for the conclusions of Gambone et al. To the extent that such assays exist at the elementary school level, observations from several thousand classrooms showing the extent of variation in instructional and social resources and the generally low level of such resources (NICHD ECCRN, 2002b, 2005), should engage the interest of many developmental psychopathologists.

Pianta (1999) advanced a theory of developmental needs and schooling that concentrates on relationships with adults and regulation of basic developmental mechanisms related to cognitive and academic performance, social and emotional development, and self-regulation that is operationalized in schools in terms of child-teacher relationships and assessed using informant report, interviews, and observations. Ladd and colleagues (Birch & Ladd, 1998; Ladd & Burgess, 1999) have also emphasized relational and social needs of children and focused on relational style as an organizing construct for understanding children's access to resources in classrooms and schools. Consistent across the Pianta and Ladd approaches is a focus on instruction and mastery support, emotional security, autonomy/relatedness, motivational needs of the child, and the value of aspects of the proximal experience of the child in school settings.

A MODEL OF TRANSACTIONAL PROCESSES IN SCHOOL SETTINGS

Drawing on the principles of the general ecological model, the elaborations of that model for school settings (Eccles & Roeser, 1998; Pianta, 1999), and the contextualist principles described by Boyce et al. (1998), Figure 13.2 depicts a model of transactional developmental processes in school settings that incorporates a multilevel view of systems and subsystems, transactional effects within and across levels of the school ecology, and an assortment of macroregulatory effects related to external forces such as school and grade transitions and accountability pressures as well as influences that could be related to genetic actions (Gottlieb & Halpern, 2002). The model emphasizes cross-level interactions as well as developmental time.

In the sections that follow, three aspects of this model of schooling—structural/resource effects, proximal processes, and macroregulatory aspects of schooling—are discussed in some detail using descriptions of research illustrative of the model's focus. The primary intent of this discussion is to

Figure 13.2 Transactional processes in school adaptation.

illuminate aspects of the school setting that can be the focus of developmental psychopathology inquiry and, in so doing, provide a means of more clearly and systematically linking developmental and education science. To the extent that the science of developmental psychopathology extends to applications intended to promote positive development, knowledge of school settings is absolutely critical to the success of such endeavors. In part, knowledge of school settings helps address the research/practice dichotomy and the problem of understanding variation in implementation and fidelity (Greenberg et al., 2001; Hoagwood & Johnson, 2003; IES, 2004a).

Additionally, knowledge of school settings is critical for a more sophisticated and comprehensive theory of development (Cicchetti & Aber, 1998). For example, developmental models now typically emphasize transactional process, but precious few of these effects are uncovered in empirical studies, in part due to limits in the ways such effects occur (and therefore can be studied systematically) and the limited range of variation that often exists in experiences of children. Schools provide ways of systematically exposing very large numbers of children who vary widely on characteristics of interest (e.g., ability, prior experience) to planned variations in experience (curriculum, etc.) that in turn vary in planned (and sometimes unexpected) ways across time. Further, examining how such variation and change in experience interact with variation and change in other important regulators of development (such as pubertal timing) opens up even more territory for important examination of transactional mechanisms. Thus, school settings have embedded within them countless opportunities for studying the transactional processes that theory posits but that remain difficult to identify. Kellam and colleagues (e.g., Kellam & Rebok, 1992) have argued that systematic implementation of intervention trials in school populations as well as exploitation of school policy, practice, and organization are fundamental strategies in developmental epidemiology. Systematic implementation of prevention trials have been suggested as strategies for uncovering developmental mechanisms (Howe, Reiss, & Yuh, 2002). In short, for a theoretical and conceptual framework that emphasizes development as a product of multisystem transactional activity, school settings provide opportunities for inquiry that allow for tests of fundamental principles.

Structural Policy and Resource Effects at Building and District Levels

This discussion illustrates two school-level features, one structural and one more process-focused: class size and

school climate/building organization and ethos. Although many more factors could be identified at this level (e.g., per pupil expenditures, grading and assessment practices), these will not be the focus of this discussion and readers are referred elsewhere. For example, demographic makeup of the district or building, leadership, school climate related to academic achievement and discipline, systematic student assessment, opportunities for staff training, and parent involvement (see Alexander & Entwisle, 1988; Newmann & Wehlage, 1995; Rutter et al., 1979) are also school-level features of some import. When teachers report high levels of support from school administrators and perceive these administrators to be strong leaders, children's achievement tends to be higher. Furthermore, discipline policies are a critical feature of the school environment as children transition to junior and senior high school, such that control-oriented policies (e.g., zero-tolerance policies) are related to lower levels of student motivation and achievement than are policies and practices that promote self-control, self-regulation, and cooperation (Noam et al., 2001; Roeser et al., 2000). School districts also vary in resources that affect children's outcomes, including per pupil expenditure, teacher experience, teacher salary, and teacher-pupil ratio, that are policy-relevant features of the school environment shown to relate to child outcomes (e.g., Gottfredson, 2001).

Class Size

Class size is one of the educational policy parameters receiving a lot of attention in the United States (e.g., Betts & Shkolnik, 1999; Ehrenberg, Brewer, Gamoran, & Willms, 2001; Finn & Achilles, 1999; Hanushek, 1999; Hoxby, 1998; Mosteller, 1995) and the United Kingdom (Blatchford, Goldstein, et al., 2002; Blatchford, Moriarty, et al., 2002). Evaluations of two class size initiatives concluded that lower class size was related to improved child outcomes (Finn, Gerber, Achilles, & Boyd-Zacharias, 2001; Krueger, 1999; Mosteller, 1995), with significant positive effects for lower class sizes on student achievement for nearly all grades tested, kindergarten through eighth (Finn & Achilles, 1999; Krueger, 1999; Nye, Hedges, & Konstantopoulos, 1999), and somewhat larger effects for children from disadvantaged households. The National Assessment of Educational Progress (NAEP) also shows that across districts and states, there is evidence to suggest that lower class size is associated with higher student performance (Grissmer et al., 2000). This finding is confirmed by evaluation of available data in Texas (Rivkin et al., 2000) and California (Class Size Reduction Research Consortium, 2001). Blatchford and colleagues' (Blatchford, Goldstein, et al., 2002; Blatchford, Moriarty, et al., 2002) work in En-

gland reports that lower class size is associated with improved child achievement (particularly in literacy), time on task, and enhanced teacher support for learning.

For the most part, social outcomes have not been examined in studies of class size (Ehrenberg et al., 2001), and little research links class size with observed classroom activities, practices, and processes (Blatchford, Moriarty, et al., 2002; NICHD ECCRN, 2004a; Pianta et al., 2002). In a recent comprehensive evaluation of the effects of class size on classroom process, children's social and academic outcomes in first grade, the NICHD Early Child Care Research Network presents results indicating the level of complexity and understanding that can be achieved when a developmental psychopathology model is applied to the study of educational problems and concerns. By adjusting outcome estimates for functioning prior to entry to school and a host of family, child, teacher, and school selection covariates, and having measures of ongoing process and classroom input to the child, this study examined class size and its effects on relative change in child outcomes in relation to concurrent effects on classroom processes. The results indicate differences both in child outcome and classroom process as a function of class size. Smaller *first-grade* classrooms (about 22 students or fewer) appeared more child-centered; they were marked by higher-quality teacher-child interactions, both instructionally and emotionally, and somewhat more disruptive behavior by children, but teachers in these classrooms viewed the children as competent and well-adjusted and reported feeling close to them. As classrooms added children they became more structured, with more frequent teacher-directed exchanges involving academic activities. Clearly, the size of the class did play a role in shaping children's social and academic experiences and, especially important, teachers' perceptions of children's behavior.

School Climate and Culture

School climate refers to the quality and consistency of interpersonal interactions within the school community that influence children's cognitive, social, and psychological development (Haynes, Emmons, & Ben-Avie, 1997). Climate influences children's confidence in their abilities (Cauce, Comer, & Schwartz, 1987) and teachers' efficacy beliefs (Bandura, 1994) and can shape teaching practices that affect children's motivation and self-views (MacIver, Reuman, & Main, 1995).

In middle school, children's positive perceptions of school are related to their motivation, achievement, and emotional functioning (Roeser et al., 1998, 2000). Middle school students who have higher levels of motivation and

emotional well-being also believe that their schools are more developmentally appropriate in teacher-student interactions, practices, and norms (this is especially important, as many middle schools are less supportive of the developmental needs of students than are elementary schools). Teacher-student interactions that lead students to feel supported by their teachers, and smaller communities of teachers and students are also important in enhancing young adolescents' motivation and emotional well-being (Roeser et al., 1998, 2000). As a result, it appears that school climate, teacher-child interactions, and children's motivations about and attitudes toward achievement are quite interconnected during the middle school years and beyond.

Reflecting the climate of the school are mental health and associated services and reforms aimed at curriculum and school management that target proximal processes, such as child-teacher relationships and instructional quality and child outcomes (see Adelman, 1996; Battistich et al., 1997; Durlak & Wells, 1997; Haynes, 1998). Toward this end, Aber, Jones, Brown, Chaudry, and Samples (1998) report on the effects of implementing a schoolwide conflict resolution program in the New York City schools. They profiled three groups of teachers/classrooms in terms of the extent of training and implementation of the program. Teachers received different levels of standard training workshops, and their use of the program was recorded. In examining the differential effects of training levels and implementation in relation to reducing aggression, stronger effects were observed for teachers who practiced implementation with only moderate training in comparison to those who received more training but implemented less. These data suggest that the effects on children of deploying a schoolwide intervention program were conditioned not by teachers' knowledge of the program but by what teachers did to implement the program, suggesting that school-level actions operate on child outcomes principally as a function of penetration to the level of proximal processes. The evaluation design in the Aber et al. study also provides an illustration of a way to capitalize on data collected as part of routine school-based assessments to study efficacy of an intervention. The school based data collected in this study included not only child outcomes but aspects of teacher and school characteristics that helped illustrate effectiveness and reveal multilevel transactions.

One source of information about school climate comes from interventions aimed at changing climate. These interventions are often aimed at changing relationships in the school and creating a sense of community (Baker, Terry, Bridger, & Winsor, 1997; Committee for Children, 2004).

For example, the goals of the Caring Communities approach are to help children "feel psychologically safe, responsibly connected to others, practice ethical decision making and self-governance in the microcosm of the classroom" (Baker et al., 1997, p. 598). These are similar to the goals of the Comer School Development Program (Haynes, 1998), which include an emphasis on caring and sensitivity of school personnel and access to the school's resources (personal and social as well as material and instructional). The Child Development Project (e.g., Battistich et al., 1997) emphasizes students feeling emotionally supported by teachers and cultivating a school climate in which emotional resources are available and flow readily as needed. By and large, results from evaluating such projects indicate that school-level values, ethos, policies, and procedures concerning social relationships and interactions do indeed alter and shape the experiences and outcomes of children in attendance (Aber et al., 1998; Battistich et al., 1997; Haynes, 1998).

In short, school- and district-level factors clearly are to be considered in developmentally informed research on schooling. Much as has been the case in research on child care, structural aspects of settings do indeed shape proximal process and child outcomes (NICHD ECCRN, 2004a), although clearly such associations are complex and perhaps conditioned by a range of teacher and student characteristics (e.g., Finn & Achilles, 1999). Designs that more strategically examine process and outcome shifts as a function of changing educational policy and structural parameters would clearly add to our understanding in this area.

Proximal Process Effects: Classrooms, Teachers, Peers

Classroom-level variables that reflect proximal process experiences of children include engaging and appropriate instruction, opportunities for problem solving, systematic use of feedback on one's performance to guide instruction, opportunities and support for peer relations and friendships, and classroom management in which behavioral expectations are stated clearly and enforced consistently (see Evertson & Weinstein, *in press*), as well as relationships with teachers and peers and status within peer networks (e.g., Gifford-Smith & Brownell, 2003; Good & Brophy, 1986; Pianta, Steinberg, & Rollins, 1995). Static factors such as teacher experience, often considered a key attribute of the value of classrooms, have shown little relation to processes such as teachers' own behaviors in the classroom,

children's reports of the classroom environment, or child outcomes (NICHD ECCRN, 2002b, 2004c; Stuhlman & Pianta, 2001). More specifically, Battistich et al. (1997) report that in a large sample of upper elementary school students, there were no significant associations between child-reported or teacher-reported perceptions of the school as a caring community (which included an index of teacher emotional support) and teacher age, number of years teaching, education, or ethnic status.

Classrooms

Programs of research establish that the kind of instructional and social interactions with adults that occur in classroom settings have reliable and detectable effects on children's achievement and social competence (e.g., Howes et al., in press; Meyer, Wardrop, Hastings, & Linn, 1993; Morrison & Connor, 2002; NICHD ECCRN, 2002a, 2004a; Peisner-Feinberg & Burchinal, 1997). Likewise, interactions with peers in school are also predictive of a range of social, psychological, and academic outcomes (Gifford-Smith & Brownell, 2003). Yet, despite general agreement on what constitutes positive teacher-child interactions and classroom processes, in observations of more than 1,500 classrooms (Bryant et al., 2003; NICHD ECCRN, 2002c, 2005; Pianta et al., 2002), the overwhelming conclusion to be drawn is the exceptional variability in learning experiences offered to children in the early grades (for specific results, see NICHD ECCRN, 2002c, 2005; Pianta et al., 2002). For example, in these studies, several thousand elementary classrooms were observed for at least one day, and although for the most part the typical child receives instruction in whole-group experiences, in some classrooms children are never taught in a whole group, whereas in others this is the mode of instruction all day. Similarly, although literacy instruction is the predominant activity offered to children, in a substantial number of classrooms children were offered no literacy activities at all. These carefully conducted observations of classroom process confirm the exceptionally variable nature of children's experiences (perhaps a confirmation of the importance of implementation variation in intervention studies) and the small links between this variation and typically assessed features of teachers such as education or experience. It does appear that more specific and more psychologically informative indicators, such as teachers' knowledge about subject matter, recent training in child development, or emotional indicators such as depression, play a more influential role in explaining variation in classroom process (Aber et al., 1998; CPPRG, 1999; Hamre & Pianta, 2004;

Pianta et al., 2003), although these factors are largely ignored in most research on classroom process.

Thus, we know from recent large-scale observational studies that classrooms are highly variable (e.g., NICHD ECCRN, 2002c, 2005), both in terms of the discrete activities offered to children and in terms of global qualities of the environment. For example, the degree to which classroom teachers make productive use of time or classrooms are well-managed ranges across the full spectrum of possibilities, even though kindergarten and first-grade classes appear, on average, to be positive and supportive social settings (NICHD ECCRN, 2002c; Pianta et al., 2002). How these specific features of classrooms shape child outcomes is of considerable interest, particularly in light of this high degree of variation. In analyses of contemporaneous associations between dimensions of classroom experience and social/behavioral functioning, children are rated as more attentive in classrooms that are characterized as socially and emotionally supportive (NICHD ECCRN, 2002c), and interactions with peers are less frequent in more structured classrooms in which teachers direct students' activities to a large degree (NICHD ECCRN, 2004a).

Yet, more careful analyses of the value-added quality of specific classroom features provides a more powerful base for inferences of the importance of classroom experience. One study from the NICHD ECCRN (2004b), examining social outcomes of children through the first 2 years of school, provides evidence of specific classroom effects and also the value of integrating school/classroom process fully into developmental studies. In this study, assessments of family and child care factors from birth to 54 months, achievement and social outcomes at the entry to school, and qualities of first-grade classrooms were used to predict social and behavioral functioning. In models used to predict relative change in social functioning from 54 months and kindergarten to first grade, the effects of home and child care on first-grade social functioning were accounted for largely by their associations with early social functioning (and not achievement) at preschool and kindergarten rather than unique associations with first-grade outcomes. Yet, after controlling for home and child care factors, more teacher-led structured activities in first-grade classrooms predicted mother's reports of more internalizing behavior, and classrooms rated as more emotionally supportive predicted lower levels of mother-reported internalizing behavior as well as more concurrently observed indicators of competence. Although it is not unique to see studies examining associations between child outcomes and classroom process, this study is unique for its *developmental* analysis

of this issue in the context of information on prior home experiences and child outcomes prior to school entry.

Relationships between Children and Teachers

Relationships between teachers and children have been a focus of educators' concern for decades. Some experts suggest that a relationship with at least one caring adult, not necessarily a parent, is perhaps the single most important element in protecting young people who have multiple risks in their lives (e.g., Carnegie Council on Adolescent Development, 1989; Gambone et al., 2002; Resnick et al., 1997). For many children, this adult is a teacher. Particularly in adolescence, as the young person begins to exercise individuation and autonomy striving, as the parent-child relationship becomes more ambivalent or even negatively charged (Steinberg & Morris, 2001), nonfamilial relationships with adults may play an important role in supporting healthy adaptive behaviors. That this is the case is suggested by studies of younger children's relationships with their teachers (e.g., Hamre & Pianta, 2001) and by surveys of adolescents (Resnick et al., 1997), but this possibility has yet to be carefully examined in longitudinal studies. Unfortunately, there are few studies of the longitudinal effects of extrafamilial adults and even fewer studies of their developmental determinants.

In terms of specific constructs pertaining to child-teacher relationships, a number of child-reported and teacher-reported dimensions can be reliably assessed and have been cross-validated in numerous investigations. Wellborn and Connell (1987) examined variations in children's perceptions on two dimensions of relationship experience, emotional quality and psychological proximity seeking, that differentially relate (in predictable directions) to teacher's descriptions of the children as well as the children's relational histories (Lynch & Cicchetti, 1992, 1997; Toth & Cicchetti, 1996). Perceived support is a key dimension of relationships between children and teachers even at older ages. When youth were asked to identify relationships that were *emotionally* supportive—someone to count on for understanding and advice—teachers were often listed in relation to this construct. In fact, a factor associated with healthy outcomes was whether youth reported having a relationship with an adult that they identified in this way, many of whom were teachers (Resnick et al., 1997). Ryan, Stiller, and Lynch (1994) reported that the child-teacher relationship as described by children's sense of felt security was particularly salient for middle schoolers. Recently, Reddy, Rhodes, and Mulhall (2003) examined longitudinal associations between

children's reports of support from teachers and demonstrated that changes in perceived support were linked to changes in middle schoolers' depression and self-esteem.

From a teachers' perspective, features of the relationship such as a sense of closeness or conflict have been cross-validated in several studies (Birch & Ladd, 1997; Cost, Quality and Child Outcomes Study Team, 1995; Saft & Pianta, 2001), from prekindergarten through fifth grade. Conflict, or negativity, in the child-teacher relationship appears to be the factor most strongly related to child outcomes when teachers' views of the relationship are being assessed (Pianta et al., 2003). Qualities of teacher-child relationships are related to children's competencies with peers in the classroom (e.g., Birch & Ladd, 1998; Howes, 2000; Howes, Matheson, & Hamilton, 1994) and trajectories toward academic success or failure (Birch & Ladd, 1996; Hamre & Pianta, 2001; Pianta et al., 1995; van Ijzendoorn, Sagi, & Lambermon, 1992), as well as with patterns of child-mother relationships (Lynch & Cicchetti, 1992) and disruptive behavior (Hamre & Pianta, 2001).

Howes and colleagues (see Howes, 2000) have established that the quality of relationships children have with mother and form with teachers (Howes et al., 1994) plays a role in children's peer competencies, albeit relationships with teachers are stronger predictors of behavior with peers in the classroom than is the relationship with parents. Child-teacher relationships show low to moderate levels of continuity in the early grades of school, at least through second grade (Howes, Phillipsen, & Peisner-Feinberg, 2000), supporting Birch and Ladd's (1998) contention that children's relationships demonstrate a coherence across relational figures and across time. In a series of descriptive studies, changes in student adjustment from year to year were correlated in expected directions: Downward deflections are correlated with child-teacher conflict, whereas upward deflections are related to child-teacher closeness (Pianta et al., 1995).

Hamre and Pianta (2001) extended analysis of the longitudinal relations between early child-teacher relationships (in kindergarten) and child school outcomes through eighth grade. Controlling for kindergarten-entry cognitive ability and problem behavior, negativity in the child-teacher relationship reported by the child's kindergarten teacher predicted achievement test scores, disciplinary infractions, and school suspensions through eighth grade, with effects on disciplinary infractions most pronounced for children who had problems in kindergarten adjustment. The effects on eighth-grade achievement scores appeared largely mediated by effects of the kindergarten child-teacher relation-

ship on achievement in early elementary school. This was the first study to report longitudinal findings for early child-teacher relationships extending into middle and junior high school.

The coordination of parent-child, teacher-child, and peer relationship systems has also been a focus of study. Lynch and Cicchetti (1992) have established that maltreated children, as a result of experiences with parents, are sensitized to seek certain relational experiences with teachers; they are less likely to form optimal relational patterns and to seek psychological proximity and support from teachers. Birch and Ladd (1996) studied teacher-child relationships extensively in early elementary classrooms and suggest that children have a generalized interpersonal style (moving toward, moving against, moving away) that characterizes their interactions with peers and with teachers. Those children who displayed moving against behaviors in kindergarten, such as verbal and physical aggression toward teacher and peers, were more likely to form negative relationships with teachers in first and second grade (Ladd & Burgess, 1999). Children who tended to move away from others in kindergarten were more likely to be rated as overly dependent by first-grade teachers, though there was less stability in these behaviors than in aggressive behaviors (Birch & Ladd, 1998). Observed conflict in the child-teacher relationship is related to less classroom participation and lower achievement over the first half of kindergarten (Ladd, Birch, & Buhs, 1999).

Harter (1996) discusses how relationships with teachers change from elementary to junior high school. As children move through these grades, relationships between teachers and students become less personal, more formal, more evaluative, and more competitive. These changes in available relationship support from teachers can be associated with more negative self-evaluations and attitudes toward learning because the impersonal and evaluative nature of the relational context in junior high does not match well with the children's relational needs at that age. Harter finds that this model particularly applies to students who have lower levels of intrinsic motivation. In this way, teacher-child relationships (which are typically viewed as potential resources for amelioration of risk) can actually exacerbate risk if they are either not positive or do not match the developmental needs of the child.

Consistent with this view of the ongoing needs of middle-schoolers for support from adult figures, teacher support has been found to be related to sixth-grade children's school- and class-related interests and to their pursuit of social goals (Wentzel, 1998, 2002). These self-beliefs and motiva-

tions in sixth grade in turn predicted pursuit of social goals and grades in seventh grade (Wentzel, 1998). Especially important, the support youth receive from their parents, peers, and teachers seemed to have additive, thus fairly independent, effects. Support from teachers was uniquely related to classroom functioning, and Wentzel (2002) suggests the possibility that support in teacher-child relationships may be particularly salient at transition points, such as the transition from elementary to middle school.

In contrast to what is known about parents in relation to their interactions with children, virtually nothing is known about teachers, particularly developmentally. Despite a general recognition that teacher characteristics and perceptions influence the practice of teaching, little is known about how individual teacher characteristics and perceptions impact the formation of their relationships with children. Kesner (2000) gathered data on student teachers' representations of attachment relationships with their own parents and showed that beginning teachers who viewed their relationships with their parents as secure were also those who formed relationships with students characterized as secure. In a related study, Horppu and Ikonen-Varila (2001) showed that beginning teachers' representations of attachment with their parents related to their stated motives for their work and their beliefs about a kindergarten teacher's work and goals in the classroom. Beginning teachers classified as having a secure/autonomous relationship with their parent(s) were more likely than those classified insecure to express motives that were child-centered as well as centered on goals for the self. Teachers classified as secure also described more complex conceptions of a teacher's work (involving social, emotional, and instructional components) and were more likely to view relationships with students as mutually satisfying (Horppu & Ikonen-Varila, 2001).

Finally, in an example illustrative of a focus on the determinants of relational processes, Hamre and Pianta (2004) examined depression as a predictor of caregivers' sensitivity. Analyses provided evidence of consistent and unique associations between caregivers' self-reported depression and the quality and frequency of their interactions with children. Caregivers reporting higher levels of depression were less sensitive and more withdrawn. Interestingly, the type or setting of care moderated this association, such that in family day care settings, more depressed caregivers were even more often negative in interactions, a finding attributable to the absence of other adults in the care setting. Thus, this report demonstrates that proximal process features of school-like settings that children experience (e.g.,

sensitivity) are associated with both structural features (such as type of care or available other adults) and psychological features of the adult in the setting (e.g., depression).

Peer Relations

Because schools are among the settings in which interactions with peers are most likely to occur, a very large proportion of naturalistic studies of peer relations take place in schools or inquire about peer relations within schools. Yet, most of these studies remain uninformed about features of the school setting that could contribute to (or be influenced by) peer relations (Gifford-Smith & Brownell, 2003). In their comprehensive review of the peer relations literature, Gifford-Smith and Brownell focus on three core aspects of peer functioning: social acceptance, friendship, and peer network status. They document the correlates of social acceptance, friendship, and peer network status in terms of associations with a range of developmental outcomes, including school dropout, delinquency, and achievement. These authors advance a perspective that notes the complex, differentiated, and interconnected linkages among these aspects of peer functioning and the ways outcome domains are differentially affected not only by standing within a particular aspect of peer functioning (such as when having a friend with shared interests is related to self-esteem or achievement motivation), but also by the linkage among aspects of peer functioning (such as is the case when low-status children who have friends are better off than low-status children without a friend).

What is striking about the Gifford-Smith and Brownell (2003) review is the extent to which the peer relations literature reflects a reliance on school settings as contexts for the assessment of peer relations (such as when gathering large samples of children's social network standing or peer nominations in classrooms and cafeterias) and that the peer contacts that give rise to social acceptance, friendship, and network status are located in schools and often regulated by school practices and policies. Thus, in a possibly profound way, what is known about peer relations is at least in part conditioned by the manner in which such relations are affected by school setting. For the most part, research focusing on the correlates of peer relations has examined associations with family characteristics and processes, other aspects of peer functioning including developmental history, and a host of outcome variables in social, personal, and achievement domains.

Surprisingly, given the extent to which peer contacts are nested in school settings, there is a lack of attention to documenting and understanding the extent to which functioning with peers is shaped by aspects of the school setting.

For example, the peer with whom a child has contact, as well as the type of contact, could vary as a function of structural elements such as classroom placement or instructional groups within the class, the size and organization of the school (Felner et al., 2001), and the availability of clubs, sports teams, and extracurricular programs offered at the school. In addition, qualities of peer relations, such as those described by Gifford-Smith and Brownell (2003), are likely to be influenced by process factors in schools such as disciplinary policies and values, the extent of emphasis on fostering positive social relationships and preventing bullying, teachers' own knowledge and skill in fostering children's successful adaptation with peers, classroom supports for social engagement and interaction, and the extent to which out-of-school time with peers is supported, fostered, and encouraged by the school and its practices. At this time, there is very little known about these connections between school settings and peer relations, despite the very large extent to which contacts among peers are embedded and distributed in school settings and processes. As at least one example of research on classroom process effects on peer relations, Hughes, Cavell, and Willson (2001) documented within classrooms that the extent and nature of teachers' interactions with a specific child are associated with the rest of the class's perceptions about that child and the likelihood of their affiliating with that child.

In addition to the ways that features of schooling may affect the nature of peer functioning, as peer relations become increasingly important in middle and high school, it could be argued that schooling processes are in turn affected by properties of peer relations either concurrently or in the past (e.g., Kellam et al., 1998). During the teenage years, adolescents spend increasing amounts of time alone with friends (Larson & Richards, 1991), and certain groups emerge, each with its own characteristics and potential for influence in schools. Crowds emerge during early adolescence as collections of peers defined by reputations and stereotypes that exert profound influence in terms of norms for their members (Gifford-Smith & Brownell, 2003). The number and types of crowds in a school can reflect the niches available for students and in turn can affect the nature and delivery of curriculum, discipline policy, and school climate in ways that shape opportunity structures (Gambone et al., 2002).

Smaller in size, cliques are groups of peers based on friendship, shared activities, and other aspects of similarity. Cliques can be input to, and output from, adolescents' need to establish a sense of identity. The strength of clique associations can be considerable, and although many teens

may not be members of a clique or may participate in more than one (R. B. Cairns, Leung, Buchanan, & Cairns, 1995), adolescents' negotiation of clique membership and conflicts in membership (for one individual or between individuals) is arguably one of the primary sources of school discipline referrals and targets for classroom/school management and bullying prevention strategies (Battistich et al., 1997).

Peer groups increasingly take on an important role through high school in terms of the value they place on academic success, their role as a stimulator of cognitive and academic skills, and the shaping of perceptions, attitudes, and goals, all of which harmonize with most schools' goals (Berndt & Keefe, 1995). Youth with a history of problematic achievement and low involvement with school gravitate toward delinquent peers (B. D. Cairns & Cairns, 1994) and are likely to be most affected by shifts in dropout policies or narrowing of the opportunity structure in schools (Eccles & Gootman, 2002; Gambone et al., 2002). Although parents help establish early trajectories toward long-term educational goals, peers are the most potent influence on daily behaviors in school, time spent on homework, and a sense of school enjoyment (Steinberg & Brown, 1989).

In sum, there is ample evidence available to confirm that classrooms operate as conduits of proximal processes that play important roles in shaping children's development. Although arguably understudied in terms of inclusion in developmental designs and analysis and understanding of determinants and description of developmentally salient features, it is clear that classrooms warrant inclusion in models of key developmental settings (Bronfenbrenner & Morris, 1998).

Macroregulations: School Transitions

It was previously noted that schools are particularly interesting settings in which to examine phenomena of interest to developmentalists in part because of the manner in which large-scale regulatory actions are enacted across variations present in populations of children. Such actions allow for the examination of the ways contextual variation moderates individual characteristics, and when examined longitudinally, the subsequent response of school contexts becomes an opportunity for studying transactions.

The transitions organized into school careers are just such an opportunity. As has been demonstrated by Morrison's use of the transition into schooling and age of entry into school as a marker (Morrison & Connor, 2002), strategically capitalizing on school transitions both allows developmentalists to disentangle confounded effects (such as

age and cognitive ability or achievement, as in Morrison's research) and to examine transactions and moderation, such as is the case when children of varying achievement or social attributes are differentially exposed to certain schooling experiences (Hamre & Pianta, 2001; NICHD ECCRN, 2004b). In present-day American schooling, the opportunities for exploiting such arrangements in schools are exceptionally rich because of the focus on regular standardized assessment of children on repeated metrics and the pressure to deploy instructional resources and programming differentially as a function of performance on such metrics. Although mental health and behavioral aspects of development do not figure prominently in these discussions, developmental psychopathologists will recognize the opportunities for examining mediated and moderated linkages between achievement and behavioral/mental health outcomes.

In the discussion that follows, the transition to elementary school and the transitions to middle and high school are discussed in relation to changes in the child's experience of school and consequences for developmental outcome trajectories.

Kindergarten and the Elementary Grades

The transition to school receives much attention as a key outcome variable in educational policy and practice in large part because it is during this period that certain outcome trajectories become established (Entwisle & Alexander, 1999), which can be increasingly unresponsive to alteration as the child progresses through school. Thus, several major research effects have targeted the period of school transition for further study, particularly for children in poverty: the Head Start Transition study (S. L. Ramey & Ramey, 1992), the National Education Longitudinal Study (Meisels & Liaw, 1993), and the NICHD Study of Early Child Care (NICHD ECCRN, 2002b; see Kagan & Neuman, 1998, for a review). In considering the transition to school as a possible deflection point in development, several points are germane.

First, the ages from 4 or 5 to 7 (roughly) mark a period of change in the "developmental agenda" in many cultures (Sameroff, 1989; Sameroff & Haith, 1996; White, 1965). Entry into the culture's system of formal education and expectations of responsibility and independence within that system is one correlate of this shift. Kindergarten is a different environment from preschool or home. Goals, demands, and the nature of the classroom environment are different, as is the ecology surrounding this new environment. Kindergarten has explicit goals for literacy, numeracy, and socialization that are not formal, stated goals of

preschool or home environments (Hains, Fowler, Schwartz, Kottwitz, & Rosenhoetter, 1989). The statement of these goals, their connection to a system of instruction, and the way they are tethered to success in later grades usher into kindergarten an emphasis on *formal instruction*, instruction that has the specific intent of raising the child's skill level. Such intent is not typical in preschool settings. Thus, children, teachers, and families experience the entrance into kindergarten as a qualitative shift (Belsky & MacKinnon, 1994; Bredekamp & Copple, 1997; Love, Logue, Trudeau, & Thayer, 1992; Pianta & Kraft-Sayre, 1999).

Interactions in the kindergarten classroom environment become increasingly intentional and focused on academic progress. As a result, interactions between children and teachers differ compared with those between children and their preschool teachers, or children and their parents. Gradually, these teacher-child relationships become increasingly influential to the child (Howes et al., 1994). Increased class size and child-to-teacher ratios characteristic of kindergarten change the nature of child-teacher interactions (Heaviside & Farris, 1993; NICHD ECCRN, 2004a), as does the philosophy underlying the kindergarten curriculum (Bredekamp & Copple, 1997; Kagan & Neuman, 1998; Love et al., 1992). Evidence suggests that the kindergarten experience, characterized by these new constraints, contributes to increased academic skills. Most children who enroll in kindergarten perform better than those who do not, and those exposed to more kindergarten may do better still (Dauber, Alexander, & Entwisle, 1993; Entwisle, Alexander, Cadigan, & Pallas, 1987).

The demands of kindergarten place stress on social and emotional competencies as well. Demands such as independence from adults, getting along with other children, recognition of and adherence to routine, and being alert and active for longer periods of time challenge the 5-year-old child. In preschool environments, teachers display more warmth than in kindergarten and are less demanding of the child in terms of formal routine and instruction (Love et al., 1992). Kindergarten teacher-child interactions emphasize cognitive skills over less academic activities and, as a result, demand more time for teaching new skills compared to guiding unstructured activities. Kindergarten teachers tend to group children differently to enhance autonomy; kindergarten children spend more time in large groups and less time in small groups, and kindergarten classrooms usually consist of more total children and more children per adult (NICHD ECCRN, 2002b, 2002c). In these ways, there are considerable differences between preschool and kindergarten environments. Children find this

shift somewhat challenging: The emphasis on academic skills and the demands to interact with a wide range of children are reported to be the most difficult aspects of the transition to school (Love et al., 1992).

Of special importance, it is at this point of entry into school that population-level screening mechanisms coincide with the contextual and expectation shifts noted earlier. Thus, just as children are experiencing this new environment with all its demands, schools are starting to screen for disabilities and increased attention is paid to identifying children in need of additional services (Ysseldyke et al., 2000). This confluence is largely responsible for a population-level rise in children identified as "exceptional" or "deviant" in terms of some level of documentation for eligibility for special education, mental health, behavioral, or supportive academic services (Hoagwood & Johnson, 2003; Ysseldyke et al., 2000). In this way, the transition to kindergarten offers a unique opportunity for developmental psychopathologists to examine how health and education policy and identification/eligibility mechanisms shape the psychological (e.g., teachers' beliefs) and behavioral (e.g., classroom interactions) mechanisms that may lead to diagnosis of disorder.

Although this discussion points out changes related to the major transition shift into formal schooling at kindergarten, regular grade-level shifts occur throughout elementary school that in smaller ways mirror the kindergarten transition. Increased formality and expectations and fewer opportunities for social and supportive contacts with teachers are among the most frequently acknowledged changes from grade to grade during elementary school.

Middle and High School

In most American communities, youth experience at least one major school transition, the transition into high school, and, including the shift to middle school, most often two during the years 10 to 18. The nature of these transitions is often linked to academic performance and behavioral competence in the prior grades, and the experience of the transition can be predictive of subsequent performance in those areas. Simply experiencing a school transition can be problematic; Simmons and Blyth (1987) reported that moving into a seventh- through ninth-grade junior high was associated with poorer school performance than staying in a kindergarten through eighth-grade school and that youth who transitioned into a junior high school were more at risk of school failure and (eventually) dropping out of school. This transition to junior high at seventh grade was also associated with a decline in females' self-esteem and in

males' sense of being victimized than for peers in the kindergarten through eighth-grade configuration (Simmons & Blyth, 1987).

Eccles and colleagues have conducted the most extensive studies of the transitions to middle school in particular, and Eccles et al. (1996, 1997, 1998; Roeser et al., 1998, 2000) concluded that the junior high school transition contributes to declines in interest in school, intrinsic motivation, self-concept, and confidence in one's intellectual abilities, particularly for youth living in poor communities and for youth already having academic and other difficulties. Thus, transitions imposed by the organization of schooling are themselves risks or stresses on development at this age and operate in much the same way, in relation to identification and production of disorder, as does the transition to kindergarten. The challenges posed by school transitions also tend to be amplified when schools are especially big (Felner et al., 2001), creating the policy/practice response to these conditions of establishing "schools within schools" to facilitate the establishment of smaller social and instructional environments for children attending large schools (Felner et al., 2001).

Keating (1990) notes that increases in achievement slow during adolescence, but that a number of factors in school settings can promote gains, such as facilitated experiences in using cognitive skills. Yet, observational research in middle schools has shown that cognitive-processing demands are often lower than in elementary school classrooms and could account for disengagement and decreases in achievement. Students' grades may drop following the transition to middle school and to high school, and this lower performance is predictive of later dropping out. This decline in grades could be attributed to stricter grading policies in middle and high schools, but also might be attributed to some students' academic disengagement and the control ethic of most secondary schools (Wigfield, Eccles, & Pintrich, 1996). Entwisle (see Entwisle & Alexander, 1999) also found that achievement test gains are relatively small, with school quality demonstrating only small effects. She concluded that adolescents' abilities and social class standing were more potent explanatory variables for educational attainment than school quality. Other contextual factors such as those related to ethnicity, gender, family, and culture exert important influences on academic achievement.

In the view of Eccles et al. (1997), young people's perceptions of their abilities and the value they attach to academic achievement are important determinants of school achievement, even when ability and past achievement are

controlled. Perceived competence also influences other motivation-related variables, such as enjoyment and interest (MacIver, Stipek, & Daniels, 1991). Such beliefs arise in part from the expectations and beliefs of parents, teachers, and other important adults.

Because risk during transition is driven by heightened complexity and developmental demands as well as the inability of schools to provide needed supports, interventions often are aimed at increasing the ability of the school to respond to children's needs by essentially reducing psychological size and complexity. Felner et al. (2001) report 40% to 50% declines in school dropout, maintenance of achievement levels, and fewer child- and teacher-reported behavioral/emotional problems for a program that creates a school within a school. Not surprisingly, teachers also reported higher job satisfaction and less burnout (see Felner et al., 2001). Common dimensions of successful secondary schools, according to Felner and colleagues, include promoting a sense of belongingness and agency, engaging families, having an integrated, quality curriculum, requiring ongoing professional development (both in curriculum content and in child development), having high expectations for students, and offering opportunities for success.

In short, transitions embedded in the organization of schools function in regular and predictable ways to transform the social and instructional environment of the setting and, consequently, children's experiences. These shifts are reflected also in the smaller, more incremental changes that take place (in American schools) when children move from grade to grade. Studies that capitalize on systematic variation in the timing and nature of how transitions are organized, as well as the variants in school transitions available in other cultures (e.g., in Norway, where classrooms remain intact for several years with the same teacher), allow for examinations of context-process-outcome links foundational to developmental theory.

Summary

Clearly, schools are as complex ecologies for development as are families or child care settings or communities. Structural features such as finances and policies related to staffing and size; process features such as classroom qualities and supports, child-teacher relationships, and peer relations; and transitional points and shifts all intersect with the trajectories of children's social and behavioral adaptation both directly and indirectly as they affect academic and cognitive functioning. The growing research literature and methodological advances in studying school effects

and school adaptation afford developmental psychopathologists the conceptual and assessment tools requisite to establish the type of interdisciplinary initiatives that truly integrate schooling within developmental frameworks. As has been noted repeatedly, the complexity and organization of schools reflect a range of contextual parameters that allow developmentalists access to phenomena that would be more difficult to study in settings that are more stable or more uniform.

CONCLUSIONS, IMPLICATIONS, AND FUTURE DIRECTIONS

Nearly 2 decades ago Good and Weinstein (1986) discussed linkages between education and psychology in relation to advancing knowledge about school effects and school adaptation. They noted that the gap between psychology and education at that time seriously undermined the scientific foundation for educational policy and practice decisions. They also noted that the mechanisms and processes underlying variation in school effects were virtually unknown, foreshadowing the recent comments of Rutter and Maughan (2002). In a somewhat parallel manner, Cicchetti and Aber (1998), in their discussion of contextualism in developmental psychopathology, hoped they would not have to review the literature in another 10 years and find such a lack of attention to sophisticated analysis and measurement of contexts of development, among them schools. The cluster of recent funding initiatives that advance interdisciplinary research focused on problems of educational significance (e.g., IES, 2004a) suggests that the challenges of meaningfully integrating education science with developmental science—conceptually, procedurally, and methodologically—loom as large now as they did 20 years ago. The primary goal of this chapter has been to provide a framework for advancing scientific progress as a result of interdisciplinarity between education and developmental psychopathology, particularly for how developmental psychopathology can foster understanding of school effects on social, behavioral, and mental health outcomes and how developmental studies in educational settings can expand understanding of process and mechanisms responsible for these outcomes. Several conclusions are evident from this review that open paths for future work and initiatives; perhaps such work may diminish the frequency of calls for linkage across disciplines.

First, there is little doubt that developmental psychopathology and education, both historically and at present, share a number of mutual interests in relation to understanding and conceptualizing school effects and adaptation

in school. Going forward, school reforms provide a ready mechanism for observing the developmental consequences of major structural and policy changes and foster a setting conducive to the application and testing of prevention and intervention strategies that could reveal developmental mechanisms responsible for outcomes of interest. Schools also afford developmental psychopathologists with an assortment of available measurements, evaluations, and definitions of adaptive (and maladaptive) functioning that are windows on outcome(s) that at times parallel, supplement, or complement analogous indicators in developmental psychopathology research. Both conceptual and methodological work is needed to more fully integrate and align school-based outcome assessments with constructs of interest to developmentalists as well as for developmentalists to assist in the broadening of what is currently measured in school accountability assessments. Looking forward, it is likely that over the next decade there will be increasing dissatisfaction in the education community with the narrowness of accountability metrics and openings will emerge for cross-fertilization of this type.

Schools also provide developmental psychopathologists with strategic opportunities to test key aspects of theory. Schools offer access to variation in a wide range of proximal process variables known to influence outcome trajectories in social, behavioral, and mental health domains. To the extent that general developmental models posit processes of moderation, schools may be one of the best places to examine such possibilities given both the variation in experience and child characteristics present in schools and schooling's mandate to in fact moderate the influence of factors such as race and economic status on achievement and life success. When considering the fact that some aspects of schooling and school adaptation are assessed at the population level, systematic integration of education and developmental psychopathology allows for the study of the dynamics of context and outcome trajectories at that level. A very concrete opportunity emerging in the not too distant future will be the use of the Head Start National Reporting System as a source of information on nearly half a million children who, after Head Start, will enter the accountability system in the public schools. Linking these outcome assessments with extant data on Head Start quality and the forthcoming focus of educational policy on teacher quality (mandated by NCLB) creates intriguing opportunities for developmental epidemiologists. Furthermore, because of variation in the temporal and structural organization of schools and the predictable, regular shifts in certain organizational features of schooling present at transition periods or in relation to accountability

assessment (some of which are predicated on child characteristics), schooling offers a way of examining transactional processes in development that can be difficult to model. Developmentally informed research in school settings also creates opportunities to disaggregate genetic confounds in analyses of contextual effects usually studied in families as well as for more sophisticated examination and interpretation of informant-based outcome assessments used so often in developmental psychopathology research.

Second, if the mutual interests of developmental psychopathologists and education researchers are to be exploited fruitfully, advances in the next several years will depend on careful attention to conceptual and methodological details and interdisciplinary links at multiple levels. Two very simple suggestions for fruitful and productive intersections are offered here: One focuses on what developmental psychopathology can offer to education; the second turns the arrow in the other direction.

At the conceptual level, educational research would benefit from applications of the general systems model to understanding behavior. The concepts of multilevel co-action and a focus on relational processes (teacher-child interactions and relationships, child engagement, peer interactions) are but two examples of this need, but there are many more. Educational theory and research, particularly in the areas of social development, lack updated understanding and theoretical frameworks to move beyond behaviorism as the predominant conceptual driver of policy and practice.

On the other hand, for developmental psychopathologists interested in examining school effects, a focus on specific aspects of the child's experiences as they link with specific aspects of the classroom environment is a more useful strategy than a focus on global features of the child or the setting. Current levels of attention in developmental research to conceptualizing and assessing school parameters are simply inadequate for realizing the potential benefits being discussed here. Developmental psychopathology needs to move beyond viewing schools as a locus of outcome assessments, or schools as sites for implementation of developmentally oriented interventions, or schools as sites for recruiting large samples, and instead look at schools as full partners in a program of developmental psychopathology research and training. One concrete and achievable objective going forward would be increased assessment of observed, child- or teacher-reported assessment of the school context in studies of social development, problem behavior, mental health, and peer relations. Absent these assessments, the extant literature on development in these domains is not sufficiently comprehensive or informed, given the available tools and evidence for school effects.

Third, the dichotomization of research and practice is a major conceptual and pragmatic impediment to achieving the benefits noted earlier. To some degree, one of the consequences of this dichotomy is the difficulty the field has with implementation in clinical trial research: Rather than increasing pressure for standardization of protocols, the findings on implementation suggest an alternative might be to more carefully understand the constraints present in the classroom or school context that account for variation. Although to some extent this problem can be addressed by informed individual investigators and teams of investigators representing the two disciplines and related fields supported by interdisciplinary funding mechanisms, movement on this issue is also predicated on support for the design and implementation of interdisciplinary training initiatives that involve schools as full partners and focus on education as a process of interest to developmental researchers (IES, 2004a). It would be helpful, in this regard, for developmental psychopathologists interested in school-age phenomena to spend time in schools in systematic training and observation of students and educators. Such efforts are reflected in the recent cluster of predoctoral training programs funded by the Institute for Education Sciences (2004b) that each addresses structural, process, and opportunity barriers to integration of this sort. Likewise, exposing educators and teachers-in-training to developmental psychopathology theory would advance a more sophisticated understanding of social and behavioral processes in schools that currently are among the more serious concerns of educators. Again, efforts at the legislative, policy, and training/credentialing levels that link training in the basic academic disciplines with the training of teachers are indicative of fields moving toward one another. Specific interdisciplinary initiatives resulting from these efforts might focus on the adult development of teachers: the ways their training and exposure to knowledge interacts with prior history and current experience to influence their interactions with children (IES, 2004a). Other work might focus on biobehavioral processes as they interact with schooling at multiple levels, an area that currently appears to have considerable promise. As these interdisciplinary efforts continue, particularly those devoted to graduate and undergraduate training, it will be critical for employment markets (e.g., research universities, foundations, school systems, government) to recognize the value not only of skills in one specific discipline, but also of the skills and understandings required to bridge and link conceptually and operationally.

The slow and difficult progress in understanding school effects and school adaptation, almost 30 years after *Fifteen*

Thousand Hours, is understandable given the complexity of development and the complexity of schooling. However, it is also quite clear that decades of research addressing these complexities have moved both the field of education and that of developmental psychopathology to a point at which productive integration is both possible and necessary for further advancement on these issues. It is abundantly clear that funding, legislative, and training mechanisms are now positioning these fields toward even further integration. One very productive future direction would be to capitalize on these shifts and movements through strategic support for integration at conferences, in publications, and through research-funding mechanisms, training programs, and models for practice and policy. Rutter and Maughan (2002) summarized progress in research on schooling and development since *Fifteen Thousand Hours* with a series of questions partially addressed by their original work that continues to press for attention. This could be interpreted as a sign that developmental psychopathology and education are doomed to be only distally and superficially linked. These questions are an invitation to deeper, more fundamental integration and interdisciplinarity that could not perhaps have been possible 30 years ago. The next decade, if work under way now continues to gain momentum, promises to be informative and may even result in a reformulation of the important, unanswered questions about school effects, school adaptation, and developmental psychopathology.

FAMILY PROCESS PERSPECTIVES: ALTERNATIVES TO PSYCHOPATHOLOGY'S EMPHASIS ON THE INDIVIDUAL

The word “psychopathology” can be translated literally as a disease or disorder of the mind. Psychological diagnosticians tend to follow the medical model when studying or treating people with “mental illness,” on the assumption that the disease or disorder is located within a person. In contrast with this individual approach, we present two related, converging perspectives on psychopathology, both of which provide a contextual analysis from the viewpoint of the family. The first, the *family systems* approach, emerged meteorically in the 1950s as an alternative conception to psychopathology's traditional focus on individuals (Goldenberg & Goldenberg, 1996). Not only did family systems theorists focus on the family relationships assumed to be involved in producing and maintaining psychopathology, but they conceptualized disorder as located in the family system. The individual diagnosed with Schizophrenia, for example, is described as the identified patient, but the pathology is located and treated in the system of relationships among mother, father, and child. The main point is not that individuals with diagnosed disorders are affected by their families, but that some family *systems* show structures and patterns of interaction that are maladaptive.

The second, *family risk factors* approach has always been a part of psychopathology, but most often as background rather than foreground. This approach attempts to identify one or two aspects of family functioning that play a central role in both the etiology and treatment of people diagnosed with disorders or experiencing high levels of psychological distress. Past and present parent-child relationships are the most frequently cited family risk factors thought to affect both normal development and psychopathology. Many theoretical perspectives suggest that patterns of positive or negative parent-child relationships tend to be repeated across generations in ways that foster adaptive functioning or psychopathology in individual family members. Mounting evidence from the past 2 decades reveals that the quality of the relationship *between* the child's parents is associated with the level of externalizing and internalizing behavior problems shown by the child. Although investigators using the family risk factors perspective occasionally examine the combined impact of two or more family risk or protective factors, their analysis is conceptu-

alized as unidirectional: the effect *of* the family *on* individual adaptation or psychopathology in a family member.

Despite the fact that family systems and family risk factors approaches to psychopathology have not usually been differentiated from one another, we believe they are worth considering separately for three reasons. First, writings about family systems and family risk factors often appear in different books and different journals. Second, although there is some systematic research on whether family systems-oriented treatments are effective, there are very few tests of propositions derived from family systems theories because their assumptions do not match well with currently accepted models of scientific research. Thus, much of what we know about families and psychopathology from empirical studies comes from research using a family risk factors perspective. Third, the two perspectives lead to qualitatively different ideas about the etiology and locus of psychopathology and views of how family members should be involved in the structure and process of treatment.

Space precludes a detailed exploration of the applications of family systems and family risk factors perspectives to all, or even some, of the major disorders listed in the *Diagnostic and Statistical Manual of Mental Disorders IV*. We trust that it will become clear throughout the chapter that there are multiple, quite different versions of family systems theories. Our preference, in agreement with Schultz (1984), is to talk about family systems ideas as a set of lenses for looking at and thinking about the development of psychopathology from a family perspective. We see both family systems and family risk factors as contextual approaches to the understanding of psychopathology rather than as coherent, monolithic theories of how psychopathology emerges and progresses.

FAMILY STRUCTURE PERSPECTIVES: THE POLITICAL CONTEXT OF FAMILY PSYCHOPATHOLOGY

In the months leading up to the United States presidential election of 2004, the contemporary state of American families began to occupy increasing attention from political candidates and political pundits. The nature of marriage and the role of marriage and family processes in children's development became significant topics of national and local debate. Postelection discussions suggested that voters' attitudes concerning some of these issues played an important role in the outcome of the election. Despite conflicting views concerning specific “family values,” neither liberals nor conservatives questioned whether families are

important or play a central role in children's well-being. The question was whether some family structures or arrangements (single-parent families, cohabiting families, divorced families, gay or lesbian families) constitute risk factors for children's development, and whether other family arrangements (primarily two-parent married families) function to protect children from a variety of biopsychosocial risks. That is, over and above the notion that family processes play a central role in individual psychopathology is the idea that some families, described in terms of demographic characteristics, are less likely to support the positive development of their members.

We have deliberately chosen to begin our review of family systems and developmental psychopathology by noting some aspects of the political/policy/practice context of the discussion about the role of families in the development of psychopathology. Our point here, which we elaborate on at the end of the chapter, is that, just as perspectives on the role of the family in psychopathology make a difference to our understanding of etiology and the planning of treatment, so the social context in which family theories and treatments are developed and promulgated has profound effects on which theories of family function shape policy decisions about how scarce resources are to be allocated for the diagnosis and treatment of children and families in distress. To remain within our space limitations and provide a focused account of family systems theory, we illustrate this thesis with examples drawn primarily from the United States. We believe that the general principles we infer and some of the specific family trends we recount (e.g., changing rates of divorce, marriage, and single parenthood) apply more broadly to Western industrialized countries and cultures.

We should note that books and papers on family systems and family risk factors in developmental psychopathology are written primarily by psychologists, psychiatrists, social workers, and other mental health professionals. Writings on family structures and social policy are more likely to be produced by sociologists, demographers, and economists. Unfortunately, the literatures on these two topics rarely take cognizance of each other. One of our tasks in this chapter is to bring the two closer together.

We begin with sections that define our central concepts: developmental psychopathology, family systems, and family risk factors. After describing where family systems and family risk factor theories fit in the pantheon of theories that compete for the allegiance of researchers and clinicians, we take a brief historical look at how these theories have changed over time. Then three longer sections illustrate how family systems and family risk factors approaches

can be applied to the understanding of developmental psychopathology.

Consistent with developmental psychopathology's concern with normal development, we examine how family processes are implicated in explaining what happens when nonclinical families go through major life transitions, both expected (e.g., marriage, parenthood) and unexpected (e.g., divorce, illness). Our focus here is not only to demonstrate correlations between family relationship quality and individual developmental outcomes, but also to elucidate the mechanisms by which families have effects on their members. We then show how formulations from a family systems or family risk factor perspective can provide value-added information, both in predicting the trajectories people follow in their journeys toward or away from diagnosed disorders, and in planning interventions for those at risk or already in distress.

The application of both family systems and family risk factor models of developmental psychopathology has been governed by a fairly traditional view of the family that was current in the mid-twentieth century, when the family systems approach emerged. Toward the end of the chapter, we step back to take a brief historical look at how families have been changing over the past century. We use this perspective to raise some questions about whether a family systems or family risk factors approach to developmental psychopathology can deal adequately with the diversity and complexity of the families they are designed to understand and treat.

We conclude with a discussion of future directions in the application of a family perspective to the study of developmental psychopathology. We offer suggestions about important theoretical and research questions that constitute promising next steps in the development of the field of developmental psychopathology. In the end, we return to a discussion of the interconnection and disconnection between psychopathology research conducted from a family perspective and policy decisions about how family researchers, therapists, and families themselves will be supported.

PRINCIPLES OF DEVELOPMENTAL PSYCHOPATHOLOGY

The entire three-volume work in which this chapter appears is devoted to the definition and explication of the principles of developmental psychopathology. Here we briefly summarize the conception of the field that guides our discussion of family perspectives.

Definitions of Psychopathology

Family systems theorists and therapists do not generally devote much attention to issues in the definition of psychopathology. Different kinds of criteria are used in making the distinction between psychopathology and normal development. All of them involve a description of individuals with extreme, maladaptive deviations—from social norms and values, from the mean of a population (a continuous view of psychopathology), or from some clinically defined ideal of psychological functioning (a categorical view of psychopathology). In this chapter, we take a rather broad view, with descriptions of family systems and family risk factor approaches to phenomena ranging all the way from statistically normative levels of stress or distress to clinically diagnosed disorders.

The Prospective Study of Pathways

A family approach to developmental psychopathology is concerned with understanding mental illness and mental health in individuals by focusing on one of the primary contexts in which individuals develop. The study of developmental psychopathology involves intensive, prospective, longitudinal analyses of four major pathways or trajectories that individuals and families may follow: (1) those at high risk for mental health problems who go on to develop disorders or debilitating psychological distress, or cause great distress to others; (2) those at high risk for mental health problems who do not develop disorders, psychological distress, or severe behavior problems as we might have expected on the basis of their risk status; (3) those at low risk who do not develop disorders, psychological distress, or behavior problems, as expected; and (4) those at low risk who unexpectedly develop disorders, psychological distress, or behavior problems. In contrast with traditional approaches to the study of psychopathology, developmental psychopathology is equally interested in instances in which risk status correctly predicts or does not predict the expected outcomes. That is, the field is intensely curious about why some people develop optimally despite risk, whereas others develop problems despite conditions that typically facilitate adaptation.

Etiology: Causal Models versus Risk Models

An axiom of the study of psychopathology is that it is essential to understand the etiology of each disorder. This task has been traditionally framed as identifying causal variables, events, or conditions (A) that are associated with

a disorder (B), precede the disorder (A before B), and provide some force or action that brings the disorder into being ($A \rightarrow B$). Furthermore, to establish causal connections, it is necessary to prove that B is not traceable to factors other than A, that there is a unique connection between cause and effect.

Providing evidence of causality in the study of families and children's development is a difficult task (P. A. Cowan, Powell, & Cowan, 1998). It is well-known that correlations alone do not provide evidence of causality, although the absence of correlations poses a serious threat to a causal claim. For example, if there is no association between the occurrence of Schizophrenia in family members and double-binding communication in the family, it is unlikely that this theory of communication-caused Schizophrenia can be supported.

Etiological formulations that attempt to establish causal explanations of disorders are based on metaphors used in pre-twentieth century medicine, which, in turn, were based on models from seventeenth-century physics. In these models, there is always a direct connection between a cause and its effect. By contrast, developmental psychopathologists have adopted risk-outcome models from the practice of public health epidemiology (Kleinbaum, Morgenstern, & Kupper, 1982), in which (1) a risk factor is an antecedent variable or condition associated with an elevated probability of a specified negative outcome in a population; (2) a protective factor is a variable or condition that reduces the probability of negative outcome despite the presence of risk; and (3) a vulnerability factor is a variable or condition that increases the probability of a negative outcome associated with a given risk.

Resilience is difficult to define. Sometimes, in cases of high risk, children and adults do exceptionally well and are described as resilient. Although resilience is sometimes conceptualized as a Teflon quality of a person, it should be interpreted more simply as a case in which risks create challenges that lead to positive outcomes.

In many cases, the predictive association between risk and outcome simply represents a correlation between the two, with no need to claim that the linkage is causal; the establishment of accurate predictors or markers is useful in identifying individuals at risk for potential problems that have a high probability of emerging in the future. In some cases, the connection can be described as a causal risk, when it can be demonstrated that a variable or condition sets a number of processes in motion that result in a given outcome. How can we determine the difference between statistical risk indicators and causal risks? The best way to establish causality is through intervention studies that use

random assignment procedures to place comparable people in intervention and control groups; we describe some examples of this approach later in the chapter. Another way is to use comparison data and statistical controls in an attempt to rule out alternative possibilities, so that causal interpretations of the data become more plausible.

In developmental psychopathology, the ideal study is one that follows individuals and families forward, tracing the paths from risks to outcomes, rather than a follow-back design that begins with the diagnosis, followed by a retrospective search for antecedents. The main problem with retrospective designs in establishing causality is that, even when they show that a presumed antecedent (e.g., family conflict) is more frequent in families with a diagnosed member, they cannot reveal whether the same antecedent is associated with many disorders (multifinality) or whether there are multiple risk factors, each of which predict the same disorder (equifinality).

Acquisition versus Maintenance

Most theories of etiology deal with what could be called the original precipitating causes of a disorder or the factors that govern its acquisition. We want to know, for example, whether extremely harsh parenting practices that border on abuse lead to the emergence of aggressive, acting-out or shy, withdrawn, depressed behavior in a child (Cicchetti, Toth, & Maughan, 2000). Equally important for clinical practice, and a central aspect of most family system theories, is the notion that regardless of how a problematic disorder is acquired, there are causal factors or risk factors involved in how or whether it is maintained. As we will see, there is ample evidence that genetic factors are important determinants of Schizophrenia and bipolar disorders (Rutter & Sroufe, 2000) and in some cases may be considered primary factors affecting whether and how maladaptive behavior is acquired. Nevertheless, even if the acquisition process is heavily dominated by genetics, there is evidence that family interaction processes can play a key role in whether gains from hospitalization are maintained or whether patients suffer a relapse once they return home (Hooley, 2004).

Prevention: Early Intervention and Treatment

Because traditional psychopathology studies begin with people who have already been diagnosed, questions about etiology are most often raised in the context of treatment. All theories of psychopathology assume that if a disorder can be described and assessed (diagnosed), and if its etiol-

ogy can be established, it is possible to design a treatment that specifically targets the risk and causal factors known to affect the course of the disorder. By virtue of the fact that studies central to the field of developmental psychopathology are often concerned with the identification of risks long before disorders are manifested, this approach is ideally suited to the conduct of prevention science (Coie, Watt, West, & Hawkins, 1993). Once risk factors are identified, it is possible to set in motion preventive interventions that minimize risks and enhance protective factors, either to prevent a problem from occurring or to intervene early enough to reduce the severity of the problem before it becomes intractable.

FAMILY SYSTEMS APPROACHES TO PSYCHOPATHOLOGY: EARLY BEGINNINGS

The task of identifying family systems perspectives on specific diagnostic disorders is a difficult one, because most of the leading figures in the field avoided the use of diagnostic terminology in their discussions, except for some general references to the diagnoses given to the identified patient. In part, then, we must infer conceptualizations of psychopathology from the ways family therapists characterized the central problems of the families they treated.

The Founding Fathers (Mostly) of Family Systems Approaches

Around the middle of the twentieth century, groups of clinicians in different parts of the United States, beginning from different theoretical premises, challenged the notion that a focus on individual psychopathology was sufficient to provide treatment guidelines for patients who were seriously mentally ill. In different ways, each group pointed to one or two central aspects of family functioning that they believed were responsible for causing Schizophrenia or maintaining the symptoms after patients returned home from the hospital. The fact that the origins of family systems approaches began with this population in mind shaped the first generation of family systems theorists and therapists.

Nathan Ackerman, a psychoanalyst heading what later became the Ackerman Institute in New York, was an early advocate of the importance of considering family risk factors in the treatment of children (Ackerman & Sobel, 1950). Fearing rejection by colleagues, he began to hint, rather than advocate directly, that this perspective suggested that family members should be seen conjointly—all together in one room. He was finally able to argue clearly (Ackerman,

1962) that all members of a household should be in conjoint treatment whenever a child is brought in for therapy. The therapy Ackerman proposed was unlike that of many subsequent family theorists because he focused on the inner dynamics of family members that made family interaction problematic. As a result, the therapist tended to conduct individual therapies in the context of the family as a whole.

Theodore Lidz and his colleagues (Lidz, Cornelison, Fleck, & Terry, 1957) at the Yale Psychiatric Institute in New Haven objected to the prevailing tendency to blame “schizophrenogenic” mothers for their children’s Schizophrenia, pointing to the fact that families of patients diagnosed with Schizophrenia were usually imbalanced in many ways, not just in the mother-child relationship. In a clinical study of families with a member diagnosed as schizophrenic, this research group found that fathers were not playing an effective parental role. Furthermore, the couple was either in a state of high unresolved conflict (marital schism) or showed patterns of avoidance of serious conflict in which one partner’s ideas were accepted overtly but undermined by the other partner, and talk about the difference was forbidden (marital skew). Lidz and his group pointed to the transmission of distorted patterns across at least three generations: from grandparents to parents to grandchildren.

Around the same time, at the National Institute of Mental Health (NIMH) in Washington, DC, Lyman Wynne (Wynne, Ryckoff, Day, & Hirsch, 1958), later joined by Margaret Singer (Singer & Wynne, 1965a), also attempted to describe families with a schizophrenic member. Wynne pointed to what he called “pseudomutuality” in all of the family relationships, not just the couple relationship. Singer and Wynne showed that the thought disorder central to the diagnosis of Schizophrenia was more likely to be displayed when patients were brought together with their family to try to come to consensus on the meaning of a Rorschach (inkblot) card, but not when patients were seen alone by the researcher. That is, the disorder seemed to be located not in the functioning of the individual but in the family as a whole. In another laboratory at NIMH, Murray Bowen (1961) emphasized the fact that although maternal or parental *distance* was often blamed for triggering Schizophrenia in their offspring, families in which members had few personal boundaries and were highly *enmeshed* or *symbiotic* were overrepresented in the population of people diagnosed as schizophrenic entering treatment (he described these families as showing an “undifferentiated ego mass”).

A group of clinicians at the Mental Research Institute (MRI) in Palo Alto, California, extends our portrait of the founding fathers, with one founding mother as part of that

group. The members represented different disciplines, with Don Jackson from psychiatry, Virginia Satir from social work, Gregory Bateson from anthropology, and Jay Haley, John Weakland, William Fry, and, somewhat later, Paul Watzlawick from various subfields of communication. Like investigators in other parts of the country, these clinicians focused on families diagnosed with Schizophrenia and came to the view that deviant communications among family members were a central problem in families with a severely mentally ill member. One of the first widely disseminated ideas from the MRI group was the “double bind” theory of Schizophrenia, in which a family member (typically a mother) gives contradictory demands in different modalities. For example, she might say to her child “Come sit by me” but react with a shudder when the child did so. In obeying one message (“come here”), the child violated the other (“go away”). Another version of the double bind is a nonverbal message that conveys “You are not to hear what I’m telling you or see what I’m doing,” with the result that after hearing or seeing what has in fact been communicated, the child has disobeyed the implicit message. What makes the double bind so binding is that other implicit messages or “family rules” prohibit the victim from leaving the field or commenting on the conflicting messages. Although it is easy to imagine that repeated, ongoing double-binding communication from one or both parents would be highly disturbing to both adults and children, the double bind hypothesis has not been empirically validated, in part because examples are often so subtle and complex that observers cannot agree about when they occur (Ringuette & Kennedy, 1966).

Bateson brought to the MRI group’s writings two different models of systems theories without making a clear distinction between them. From Bertalanffy (Bertalanffy & Woodger, 1962), a philosopher and biologist who developed what he later called general system theory (Bertalanffy, 1973), Bateson drew on the central idea that systems have self-regulating properties. That is, there are internal mechanisms that operate to pull the system back when too much change has occurred, or push forward when more change is needed. Bertalanffy’s model was based on living biological systems, which he described as open and always capable of moving toward new organizations. Bateson also used models and metaphors from the field of game theories (Von Neumann & Morgenstern, 1953), which assume that bargaining takes place in a zero-sum environment (if I win, you lose, and vice versa), and from cybernetics (Wiener, 1961), a field in which machine systems were designed with deviation-reducing mechanisms to bring about a return to homeostasis whenever dysregulated subsystems

threatened to drive the machine out of control. These systems are not necessarily open in the same way that biological systems are. Once some change has been introduced into the system, homeostatic mechanisms operate like thermostats to bring the organization back to a prior state and are centrally important in explaining maladaptation and resistance to change. That is, within family systems theories are embedded two quite different models of self-regulation, one of which, the cybernetic example, emphasizes stability much more than change.

Why do some families continue to repeat patterns of behavior that are unproductive or destructive? Forces within the system tend to spring into action when new behavior emerges in ways that return the family to the previous homeostatic balance or set point. This formulation helps to explain why family therapists are so active compared to psychoanalytic colleagues who treat individuals. Unless the therapist disequilibrates the family with some dramatic statements, gestures, or homework assignments, the homeostatic properties of the system will frustrate the family's stated wish for change and frustrate the therapist's desire to help them change by introducing a countervailing force that resists the family's tendency to return to the tried and true.

In our view, one of the last major figures in the early origins of family systems theory is Salvador Minuchin. His initial book, *Families of the Slums*, cowritten with Montalvo, Bosman, and Schumer (1967), and his creation of the Philadelphia Child Guidance Clinic as a training center for family systems treatment helped to demonstrate that family systems principles could be applied usefully to families with a wide range of problems in a wide range of economic circumstances.

Defining Properties of Systems

Despite differences in the focus of their work, the early family systems theorists converged on a set of principles that defined the systemic approach (see Wagner & Reiss, 1995).

Wholeness

A system is composed of elements (parts) and a whole, with patterns of connections among the parts and between each part and the whole. In family systems theories, the elements are often individual family members. Each is in a relationship with each of the others, but together they constitute a family with a unique set of properties. The best-known principle describing family systems is that the whole is different from any single part and from the sum of its parts. In family terms, it is not possible to predict the behavior or level of adaptation of an individual by considering

him or her in isolation; one needs to know about the context of the individual in his or her family, the pairwise relationships among the members, and how the system functions as a whole. The father and the mother may not get along with each other, and at least one of the parent-child or sibling pairs may vibrate with unresolved conflict, but we cannot conclude that this family is dysfunctional or that the child is at risk for mental illness, because from the limited information given here we do not know what happens when all the family members get together. It would make a great difference to the well-being of the children in the family whether, for example, the parents continue their escalating arguments or put aside their squabbles successfully when the child is present, or whether one parent compensates for the fact that the other parent and the child are not getting along by being exceptionally nurturant with the child.

Locus of Problems

Problems are located in the system, not in individual members. The family member brought into treatment because of highly deviant, hostile, or anxious behavior is regarded as the identified patient; other family members have designated this person as the problem, but the therapist locates the pathology in the family as a whole and helps the family to do the same.

Subsystems

Beyond the contrast between the system as a whole and the individual family members, it is necessary to be aware of how family subsystems operate. Families in which one child is allied with the mother and distant from the father, or the couple fail to work together, are quite different from families in which the couple forms a tight bond that excludes close relationships with the children.

Boundaries

Around each subsystem is an invisible enclosure called a boundary (Wagner & Reiss, 1995). One of the key defining properties of subsystems is whether the boundaries are rigid or permeable. Rigid boundaries denote subsystems that are disengaged from each other (e.g., the father has difficulty becoming included in the mother-son relationship). Families with rigid boundaries tend to promote authority and autonomy at the expense of closeness. At the other end of the adaptation continuum, boundaries can be so diffuse and permeable that subsystems become enmeshed, as, for example, when children occupy the attention of their parents so constantly that there is no separation between the life of the couple and the life of the children.

Circular Causality

We have noted that traditional scientific models and models of psychopathology describe causality in linear terms ($A \rightarrow B$) and that it is difficult to obtain evidence in support of linear causal claims. Family systems theories make the assumption that causality is *circular*. There is mutual regulation in that change in one person in a relationship can trigger a change in the other so that changes are simultaneous ($A \leftarrow B$), or change can take place in a reverberating chain ($A \rightarrow B \rightarrow C \rightarrow A$). If this is so, it does not always make sense to try to find out which came first, but rather to intervene to change the relationship patterns.

Structure and Process

There are two kinds of questions one can ask about families: How are they structured or organized, and how do they function? The answers help us understand how families operate to produce both stability and change in the system over time. Although the comparison is oversimplified, the same questions can be asked of a battery-operated toy that has not yet been turned on. Structural questions include, How do the parts fit together? Process questions include, What does it do once you turn on the power? Structures do not exist independently of processes. V. K. Johnson (2005, p. 256) notes that, "as dimensions of family life, family process and family structure can be thought of as two conceptually distinct lenses applied to the same set of phenomena." Structures are like static photographs or blueprints that diagram the formal relations between the parts and the whole, such as whether the parts are connected. Structural descriptions of families could include size of family; whether the parents are unmarried, married, separated, or divorced; how many members are in each subsystem; and whether communication proceeds from the top down or occurs with each person having an equal opportunity to communicate. This last sounds more like a process issue, but from this description we do not have any idea about how people talk to each other. Rather, we have simply described an aspect of structure that could be seen in a static organizational chart in a corporation.

The process aspect of a system refers to dynamic qualities that are often assessed in self-report questionnaires or interviews. A more direct way of assessing the dynamics requires videotape or other devices that allow observers to record the quality of interactions as they unfold over time. Process descriptions of families could include the quality of relationships (including closeness and distance, unresolved conflict, parenting style) and the permeability of boundaries. Although it is difficult to distinguish between

structural and process levels of analysis, it can be useful to try to do so. For example, data concerning family structure (cohesion and organization) obtained in a nonclinical study of families during the preschool period contributed independently to predicting children's behavior problems in first grade, over and above observational data on the quality of marital and parent-child interaction processes (V. K. Johnson, Cowan, & Cowan, 1999).

We should note here that the concept of structure in family system theories has a different meaning from the term as sociologists use it. The similarity is that both focus on the organization of the family. Family systems theorists use structure to refer to the way family processes are arranged. Sociologists use the term to refer to different family forms described by legal bonds, living arrangements, and kinship: cohabitating, married, separated, divorced couples or single-parent families, two-parent families, and stepfamilies.

Homeostasis

We described the biological and cybernetic models that researchers at the MRI used to represent homeostatic properties of family systems. What is important about the concept of homeostasis, even when it is exemplified by a change-resisting cybernetic model, is that the system operates in self-regulating ways that can amplify or reduce the power of external stressors to affect the quality of family life.

The Novelty of the Early Family Systems Approach

Some assumptions of family systems theory are so well accepted today that it is difficult to conceive of how new they were 50 years ago, when most adult therapy was individual (although there were couples counselors and therapists) and when most children were treated in play therapy, with their parents as adjuncts to the treatment. Of course, psychoanalysts spent a great deal of time focusing on how past experiences in the family of origin operate to restrict ego and superego functioning in the present, but it would have been unthinkable (and may still be in orthodox psychoanalytic treatments) to bring the parents into the room with the child or adult patient in an effort to reconstruct the present relationship so that it functions more supportively to both generations. Child therapists in the mid-twentieth century certainly assumed that families were important, but they generally conceived of parents (mothers) as adjuncts in the treatment who could provide contextual information not available during the play therapy session or be educated about their role as a parent (A. Freud, 1965; Winnicott, 1987). Marital conflicts were often noted, and referrals for

couples therapy made, but marital therapy or direct intervention in the three-generational transmission of family patterns was not included in the job description of the child therapist. The notion that child therapists may have been treating the identified patient but not intervening where the problem was located was not a part of therapeutic discourse inside or outside the consulting room then, nor is it part of therapeutic discourse in most child treatment settings today.

FAMILY RISK FACTOR APPROACHES TO PSYCHOPATHOLOGY: EARLY BEGINNINGS

In accounting for the emergence of psychopathology in a child or adult, relationship patterns from different family domains can be considered possible risk or protective factors that affect children's adaptation or maladaptation; qualities of parent-child relationships (Steinberg, 2001), couple relationships (Cummings & Davies, 1994), and intergenerational relationships (Caspi & Elder, 1988) top the list. Although genetic risk factors are usually considered in opposition to family and other environmental risk factors, as in the contrast between nature (genetics) and nurture (family; Rutter, 2002), we view the transmission of genetic materials from parents to children as an inherently family-based process, even when the transmission is accomplished through sperm donation or other artificial means. The pattern of genes transmitted and combined in the new offspring is essentially an outgrowth of family patterns associated with the two biological parents. Let us emphasize that, in contrast to the family systems emphasis on the family as the unit of analysis and the locus of pathology, the family risk factor approach assumes that one or more risk factors combine to produce psychopathology in the individual family member.

The family risk factor approach to psychopathology has both a long and a short history. One can infer a family factors approach to psychopathology from the Greek plays and myths used by Freud to illustrate his own psychodynamic views. While the Greeks placed great weight on fates, the gods, and literal *deus ex machina* forces that affect men's and women's behavior, the Oedipus, Electra, and Medea stories present vivid examples of how family struggles can result in destruction and madness in parents and their offspring.

Prior to the emergence of family systems theories in the 1950s and 1960s, psychodynamic theories suggested that normal development involved identification with one's parent of the same sex and internalization of his or her value

judgments as necessary; failure to complete this identification was viewed as a prime risk factor for psychopathology (S. Freud, 1905). Behavioral theories promulgated by Watson (1928) and others supported the idea that how parents reinforced and punished their children played a central role in producing either well-adjusted or maladjusted children. At midcentury, however, research on children's development was remarkably *acontextual*, with Gesell (Gesell, Ilg, Learned, & Ames, 1943) and Piaget (1950) paying virtually no attention to parents, and both Sigmund and Anna Freud (1965; S. Freud, 1938) focusing only on the child's internalizations, not on parental behavior, in attempts to understand children's cognitive, social, and emotional development. With the possible exception of attachment theories (Bowlby, 1961) studies of variations in parenting styles with normal children stimulated by the work of Baumrind (1971), very little systematic empirical research focused on family relationship qualities and children's adaptation. As we show, most of the growth in the family risk factors approach to developmental research occurred toward the last third of the twentieth century.

WHERE FAMILY SYSTEMS AND FAMILY RISK FACTOR THEORIES FIT IN THE PANTHEON OF PSYCHOPATHOLOGY THEORIES

How are family systems and family risk factor approaches similar to and different from the other main developmental psychopathology theories? One of us (PAC) had a professor who taught a course in theories of personality and each week covered a new theorist in class. Instead of recounting what the theorist was trying to tell us, he always began with the questions the theorist was trying to answer, demonstrating that theorists differed not so much because of fundamental disagreements in their claims, but because of differences in their questions, focus of interest, and level of analysis. The professor's approach assumed that each theory had a corner on the truth and that there are many valid perspectives on the explanation of adaptation and psychopathology.

To the extent that we can generalize about a field, the assumption that there may be many roads to Rome is not widely accepted in the study of psychopathology. It is as if students entering the field are brought to a market bazaar, with sellers hawking their wares, each saying, "Buy my bracelets and ignore the merchant in the stall next to me. The ornaments on his bracelets are colored glass but mine are precious jewels." Is the field of psychopathology really as competitive and absolute as this? Not in textbooks,

where writers acknowledge in measured statements that there are many valid approaches to understanding what goes awry in development. In practice, however, many diagnosticians and therapists focus on the individual and pay relatively little attention to the individual's relationships with family, friends, and work, unless those topics are raised by the client in discussing current problems. Child therapists pay attention to the relationships between mother and child but tend to ignore both the father and the relationship between father and mother. Many biologically oriented therapists dispense drugs but spend minimal time talking with the patient, and many psychodynamically oriented therapists focus on talk and avoid prescribing drugs. Most behaviorally oriented therapists would not spend therapeutic time discussing inner defense mechanisms of parents or children, whereas nonbehavioral therapists rarely suggest systematic reinforcements or "time-out." That is, emphases in the therapist's theory of psychopathology shape the content and structure of both assessment and therapeutic practice.

In this section, we present schematic models that summarize answers to two major questions raised by researchers and clinicians who attempt to understand the role of the family in developmental psychopathology: Which domains of family life are necessary to examine when we assess families? and How do we understand both change and stability within each of these family domains?

A Six-Domain Family Risk Model

Until the 1980s, most studies of family risk factors focused on one domain of the family at a time, although some assessed that domain in multiple ways. In 1984, Belsky proposed a three-domain model that included the personal psychological resources of the parents, characteristics of the child, and contextual sources of stress and support outside the family as determinants of parenting quality leading to children's developmental outcomes. In the same year, Heinicke (1984) proposed a different three-domain model that included individual, marital, and parent-child factors in the prebirth period to predict postpartum adaptation in both mother and child. Our own five-domain model (C. P. Cowan et al., 1985) hypothesized that children's adaptation to elementary school could be predicted by a combination of information from five aspects of family life: (1) the individual personality and adaptation of mother, father, and child; (2) couple relationship quality; (3) parent-child relationship quality; (4) intergenerational family patterns; and (5) the balance of social support and life stress in family members' relationships with people

and institutions in the larger society. Because our research focused on the parents' relationships with their first child, we ignored an important sixth domain: sibling relationships (see Figure 14.1).

Recent evidence from our Schoolchildren and Their Families Project (P. A. Cowan, Cowan, & Heming, 2005) indicates that each of the first five domains assessed in the year before the oldest child enters kindergarten contributes unique variance to the prediction of the child's academic achievement and externalizing and internalizing behavior in kindergarten and first grade; taken together, these family risk measures account for substantial amounts of variance—often over 50%—in the child's adaptation to school. The design of our studies and the choice to assess multiple family domains using multimethod, multiperspective assessment tools (interviews, questionnaires, and observations of family interaction) was directly influenced by family systems theories as we described them earlier. Nevertheless, with only a few exceptions in which we examined family-level functioning (V. K. Johnson et al., 1999), our research designs are more consistent with a family risk factor model than a family systems approach because we look at predictions *from* family functioning *to* children's outcomes. As we will see, there is ample evidence from many studies in support of the hypothesis that adaptation or maladaptation within each of these domains accounts for substantial variance in child and adolescent functioning.

Figure 14.1 Six domains of family life involved in children's psychopathology.

A Nine-Cell Model of Alternative Explanations of Stability and Change in Each Family Domain

To understand and treat psychopathology in an identified patient, family systems theorists want us to look at the whole family, and perhaps at some of the subsystems outlined in the six-domain model. In part, their insistence on focusing on the family as a whole was stimulated by their frustration with the fact that traditional theories of psychopathology did not lead to therapies that produced change reliably (especially in patients with severe mental illness). To illustrate how family systems theories have come up with answers that are quite different from most other theories of psychopathology, we examine the following basic question: What produces stability and change in individuals, relationships, and family systems?

Why do some individuals or families show excessive resistance when situations call for change (e.g., they are unresponsive to reasonable social demands), whereas other individuals or families show excessive sensitivity to change (e.g., instantaneous reaction to the changing emotions of others)? Theoretical answers to these questions vary along two conceptual dimensions. The first dimension describes the preferred level of analysis of the theorist: Does he or she look for explanations of stability and change in biological, psychological, or social aspects of the person? The second dimension describes whether the source of change is considered to be internal, external, or interactive. Combining these dimensions yields a matrix of nine major factors affecting stability and change, each located in a different “cell” (see Figure 14.2). Each cell, then, contains a different type of theory.

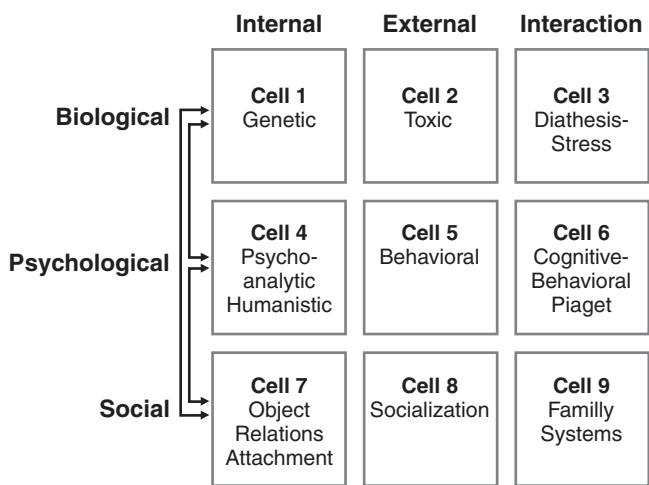

Figure 14.2 The 9-cell matrix: Alternative theories of stability and change.

Within each cell, theorists generally choose the same answer to questions about explaining normal development, explaining psychopathology, and speculating about what kind of intervention would be necessary to address problems as formulated by the theory. For example, theorists who assume that internal factors that govern change and stability shape the emergence of normal development also assume that internal conditions affect the emergence of psychopathology; not surprisingly, these theorists assume that interventions focusing on internal factors (biological functioning, defense mechanisms, cognitive schemas) should be central in whatever treatment is provided. That is, within each cell, the answers to fundamental questions about stability and change tend to come in “boxed sets.”

We should state at the outset that the basic assumptions of family systems theories are consistent with social interactional theories of stability and change (cell 9). Relationships are central. Stability or change occurs as products of interactions among individuals and subsystems in the context of the family as a whole. We can now locate other competing theories with reference to this cell. We will show that the family risk factors approach appears in a number of cells, depending on the level of analysis and the theorist’s reliance on external or internal theories of change. Although our descriptions highlight the differences between cells as if they represented mutually exclusive choices, we know that the theories in different cells differ in emphasis and do not represent categorically distinct approaches to developmental psychopathology.

Biological Level of Analysis

Biological factors in development can be found inside the person, in the environment, and in the interaction between the two.

Internal

In this cell, theorists assume that the path toward normal development is regulated by a system of genetic, biochemical, neurophysiological, and physical processes operating within individuals. If they malfunction, these same processes are invoked as determinants of psychological disorders such as Schizophrenia, depression, and antisocial personality. Theorists, researchers, and clinicians with a biological internal perspective often assume that biologically caused disorders will respond best, if they respond at all, to biological treatments such as the administration of psychoactive drugs. Because it is not possible to intervene at the level of genetic processes or brain functions, at least not yet, the biological internal view tends to

emphasize stability and resistance to change and to present a somewhat pessimistic picture of the possibility of treatment. If a disorder is inherited, the message seems to be, interventions can reduce the expression of basic symptoms but nothing much can be done to change the underlying disorder. We will see that this pessimism is unwarranted on both logical and empirical grounds.

External

So pervasive that it is not always acknowledged, the physical environment plays a central role in normal development (e.g., nutrition, clean air). Malnutrition and chemically toxic conditions (e.g., lead poisoning) can also cause psychotic reactions or extreme behavior disorders (Zetin, Stasiak, Pangan, & Warren, 1988). From the biological external perspective, intervention should be directed toward the elimination of environmental deprivation or toxicity.

Interaction between Physical Environment and Biological Factors

A strictly internal view of biological factors in development is outmoded. Internal biological processes are always influenced by external biological, psychological, and social events. Genetic and neurological processes unfold within environmental niches that influence whether risk factors will be expressed in behavior. For example, even if brain scans obtained through functional magnetic resonance imaging (fMRI) show differences between groups of patients diagnosed as schizophrenic and nonschizophrenic, we do not know whether the brain (mal)function generated the schizophrenic behavior or whether biopsychosocial stressors over time led to the brain malfunction (Kandel, 2000). From the perspective of cell 3, intervention involves alterations in the biologically based functions of the individual along with shifts in the external environment. A good example of this perspective is the treatment of children with Attention-Deficit/Hyperactivity Disorder (ADHD) with a prescription of Ritalin, along with an extensive reduction of stimulation in the children's school environment (Hinshaw, 1994).

Psychological Level of Analysis

Development can be shaped by psychological forces within people, by behaviors of others directed toward them, and by the combination of internal and external psychological events.

Internal

Given a "good enough" psychosocial environment (Winnicott, 1987), forces from within unfold to produce normal development. In this cell are the humanistic theorists (Maslow, 1962; Rogers, 1961), who assume that all human beings move toward self-actualization unless they are prevented from doing so, and psychoanalysts (e.g., Erikson, 1980; S. Freud, 1938), who assume that stages of development (oral, anal) unfold on a biologically given timetable. For these theorists, psychopathology arises when natural developmental forces are disrupted (often, though not always, by parents) and the child or adult develops internal defensive armor that may temporarily reduce anxiety but impedes the exploration and risk taking necessary for developmental progress to occur. From the perspective of cell 4, intervention involves the provision of a safe holding environment in which destructive defenses can let down long enough for normal development to move forward.

External

In this cell are the familiar socialization theories (Baumrind, 1989) and behavioral theories (G. R. Patterson, 1982) that look to parenting styles or specific patterns of reinforcement by parents or other significant adults as the forces that shape normal development. According to this view, behavior that deviates from the norm, including Autism, Schizophrenia, depression, and antisocial behavior, results from conditions in which socially inappropriate rather than appropriate behavior has been reinforced.

Psychological external theories, especially the behaviorist examples, make a point of distinguishing between acquisition of behavior and its maintenance. Therapists with a traditional behavioral perspective acknowledge the importance of establishing etiology to create new prevention programs, but they focus more of their efforts on changing the physical and social environmental patterns that maintain the behavior over time than on altering the psychological makeup of the person. Their theories of change lead to clear instructions to therapists to avoid searching for the origins of current problems in early family experiences and focus instead on what is maintaining the problematic behavior now. The most popular example of psychological external theories applied to interventions are parenting classes, self-help books (Dinkmeyer & McKay, 1982; Ginott, Ginott, & Goddard, 2003; Gordon, 1980), and behavioral parent training interventions (Forgatch & DeGarmo, 1999; Webster-Stratton, Reid, & Hammond, 2001) designed to provide parents with skills to manage their children's aggressive and problematic behavior more effectively.

Interaction between Internal and Behavioral Psychological Factors

Even before family systems theories emerged in the 1950s, it was clear that both the nature of the child and the quality of parenting had to be taken into account to understand normal development and psychopathology. Parents should not get all the credit when their children turn out well or all the blame when they turn out badly. Children are agents of their own development, and the engine driving fathers' or mothers' parenting behavior is sometimes located in the child (Bell, 1968, 1988). Children's age, sex, personality, and temperament influence how mothers and fathers respond to them, just as parents' behavior influences how their children respond in return.

Piaget's (1967) theory of child development provides a good example of an interactive theory of development. As long as children's cognitive level is adequate to handle the environmental challenges they face, they can assimilate the stimulus into existing cognitive structures and respond appropriately, so that no change is necessary. When an unfamiliar stimulus or difficult problem occurs, disequilibrium follows and the child must accommodate (change his or her strategies to meet changes in environmental demands). As the child attempts to establish a new equilibrium between assimilation and accommodation, one possible outcome is cognitive reorganization at a new and higher level of intellectual functioning. Piaget's own emphasis was on interactions between the child and the physical environment, but it is clear that parents (P. A. Cowan, 1978) and peers (Piaget, 1962) also play central roles in providing external stimulation that helps to produce developmental change. Piaget himself was not much interested in psychopathology, but some of his associates (Inhelder, 1968; Schmid-Kitsikis, 1973) attempted to apply his theory to describing and understanding deviations from normal development. In general, they attempted to explain failures in developmental progression as resulting from imbalances in assimilation and accommodation (see P. A. Cowan, 1978), an internal perspective similar in form to the social interaction theories espoused by family systems theorists.

Another approach to psychological interactive models of change can be seen in cognitive-behavioral theories (Reinecke, Dattilio, & Freeman, 2003). In a traditional behavioral approach, it is assumed that manipulating the stimulus should produce a change in the response (external psychological cell). However, the child's or adult's *appraisal* of the stimulus also plays a role in his or her subsequent behavior (Lazarus & Folkman, 1984). For example, parents with high levels of conflict tend to have children who are

more aggressive or depressed than children of parents with low levels of conflict, but this linkage is more likely to occur when children blame themselves for their parents' fights (Grych, Fincham, Jouriles, & McDonald, 2000).

All psychological interaction theories of change assume that there is some optimal level of fit and an optimal level of mismatch between the external forces of the environment and the internal structure and function of the child. Positive developmental progress is more likely when there is an "optimal mismatch" between the demands of the environment and the demands of the child. Vygotsky (1978) described a similar concept of "scaffolding" (Wood, Bruner, & Ross, 1976), in which parents move in at the appropriate level to help a child who is having difficulty solving a problem, and then move out once the child is on the right track.

Social Level of Analysis

At the social level of analysis, development is affected by relationships—internal representations, social transactions, and a combination of social interactions and how they are represented by the individuals involved.

Internal

It is not immediately clear what a social internal theory of stability and change should look like, because the idea that social relationships influence both normal development and psychopathology seems to be incompatible with the notion that *internal* forces are the primary determinants of both stability and change. What resolves the dilemma is the notion from both object relations (Klein, 1932; Kohut & Wolf, 1978) and attachment (Bowlby, 1988; Main, Kaplan, & Cassidy, 1985) theories that an inner symbolic representation or schema of a primary relationship, usually formed early in life and typically focused on the mother-child relationship, operates as a template that shapes expectations and behavior in the significant close relationships that one establishes over the life span. Working models characterized as secure, because they contain the assumption that a loved one will provide a secure base to protect the child from the threat of loss, facilitate normal development. Insecure working models (defined later in the chapter) lead to various forms of psychopathology (Sroufe, Duggal, Weinfield, & Carlson, 2000). Therapists adopting the social internal perspective on psychopathology attempt to change insecure working models, in part by providing a safe, secure environment in which clients can use the relationship with the therapist to gain perspective on their early relationships and develop the security needed to explore current and new inti-

mate relationships in more productive ways (Klerman & Weissman, 1986; Mattinson & Sinclair, 1979).

External

In the psychological external cell (5), we described examples of how a parent's behavior provides reinforcement or punishment for a child's behavior. In the social external cell, we include socialization theories in which family and peer relationships (social support) and social institutions outside the nuclear family (workplace, government) affect whether individuals move toward normality or pathology in their life trajectories (Parke & Buriel, 1998). What differentiates this approach from the interactive position in the next cell (9) is that the effects are thought to be directional (acting on the person) rather than bidirectional (positing circular causality, a central tenet of the family systems approach). Theorists who emphasize social relationships and social system forces as causal risk factors that affect the development of psychopathology usually turn to social change programs in an effort to reduce or alleviate psychopathology in individuals (Sarason, 1974; Weinstein, 2002).

Interaction between Internal and External Social Factors

Family system theories represent the quintessential example of social interaction theories of stability and change. "The system" is the major unit of analysis, although subsystem balances and imbalances are important. Reciprocal interactions among individuals, and the reciprocal impact of relationships on relationships, create the conditions for normal development or psychopathology, with treatment optimally conducted with all the players in the room at the same time.

Six Domains and Nine Cells

The six-domain model describes where the investigation of psychopathology is focused, on the system as a whole or on one or more of the subsystems. The nine-cell model helps us to understand the multiple ways of conceptualizing stability and change within each domain, with corresponding theories of how adaptation or psychopathology emerges. For example, within the couple domain, it is possible to account for stability or change at a biological level (the impact of illness), a psychological level (the impact of mismatched personality styles), or a social level of analysis (the impact of dysregulated expression of negative affect). Theories can be focused on internal factors in change (attachment processes), external factors in change (cultural expectations), or the interaction between the two (what

happens when a man with an insecure model of attachment marries a woman with a secure model of attachment and is unable to fulfill the culturally stereotyped strong, silent, protector role?).

Our nine-cell classification of theories of change and stability helps us to make a more differentiated distinction between family systems and family factors approaches to developmental psychopathology. We have reserved cell 9, the social interactional cell, for family systems theories with their emphasis on normality and psychopathology as a gestalt (whole) formed by the system of reciprocally interacting relationships. Especially in the early years of family systems theories, the focus was primarily on that system and not on the individuals within it. These homeostatic theories were better able to explain why families remain stable than why they change. As we will see, because a focus on the system as a whole was not always efficacious in producing family change, some aspects of family risk factor theories have been incorporated into family treatments.

Theories that focus on the family risk factors that affect individual psychopathology appear in all of the other cells—in genetic and other biological forces (cell 1); household environment effects (cell 2); the interaction between biological and physical environment factors (cell 3); an individual's defensive system, erected to provide relief from anxieties created in the family, or an individual's appraisal of family members' behavior (cell 4); parenting behavior (cell 5); the match between parental behavior and the child's psychological organization (cell 6); working models of intimate family relationships (cell 7); and the impact of family relationships on the individual (cell 8). Each of the factors considered separately and all of the factors in combination can affect the pathways that individuals take toward or away from adaptive functioning.

In the examples of interactive theories of change presented earlier, we described interactions between external sources of stability and change *within* biological, psychological, or social levels of analysis. Physical environments have different effects on people with different genetic constitutions. Parenting behavior may be interpreted differently by children who have different interpretations of what their parents are trying to do. Family relationships may play out differently with individuals who have secure or insecure working models of relationships. It is easy to see, however, that biological processes interact with psychological and social factors to affect adaptive and maladaptive development. For example, a diathesis-stress model of psychopathology (Gottesman & Shields, 1971) suggests that genetic and other biologically based predisposing factors (the diathesis, or vulnerability) develop into

full-blown psychopathology only when triggered by severe social stressors and psychological vulnerabilities.

Independence of Etiology and Treatment

Our discussion of theories located within each cell pointed to parallels among theories of normal development, psychopathology, and intervention because this is the prevailing assumption of those who apply theories of development to their intervention programs. We believe it is necessary to challenge the assumption of lockstep consistency between etiological and intervention theories on both logical and empirical grounds. The issue becomes clearer if we consider two “thought experiments.” First, let us assume that variations in genetic makeup actually cause a very high proportion of the variation in level of adaptation assessed at a given point in time. It is still possible that psychological or social interventions will produce positive change in behavior. Just as height, which is highly heritable, is profoundly affected by diet, so an individual’s level of psychopathology, regardless of the causal factors involved, can be changed by environmental manipulations.

Second, let us assume that instead of genes as etiological factors, variations in parents’ reinforcement patterns cause a very high proportion of the variation in level of adaptation assessed at a given point in time. It is still possible that, because the patterns of interaction have been persistent and cumulative over the years, no known psychosocial intervention can produce positive change. Furthermore, well-managed drug treatments might provide conditions in which further psychosocial treatment will now be effective.

In sum, although we have followed standard practice by associating theories of etiology with theories of intervention, we emphasize that one’s theory of how a disorder was caused does not necessarily dictate the most appropriate treatment approach. More specifically, if we find evidence that family risk factors play a role in causing or maintaining the disorder, this does not exclude biological or physical environment interventions as part of the treatment process. And even if we find evidence that genetic, brain, or physiological factors play a role in causing a disorder, we should be open to including family members as part of the treatment plan.

If our theory of treatment does not necessarily follow from our theory of etiology, why spend so much effort in attempts to identify the causes of a disorder? Because without a well-supported etiological or risk factor theory, it will be impossible to plan a program to prevent the occurrence of a disorder or to identify individuals and families in the early stages before the disorder reaches diagnosable levels.

CHANGES IN FAMILY SYSTEMS AND FAMILY RISK FACTOR APPROACHES TO PSYCHOPATHOLOGY OVER THE PAST 50 YEARS

Family systems theory has come a long way since its origins in the mid-twentieth century. As we look back, we see an interesting cycle in which the early family systems theories of the 1950s and 1960s had a delayed but important impact on family risk factor research in the 1970s and 1980s, which in turn began to influence a move toward integration of quite different family systems approaches to diagnosis and treatment at the end of the century.

New Family Therapy Gurus and New Schools

New charismatic family therapists joined the club created by the early founders of the field, each using the early family system theories as a starting point but offering a slightly different central idea of what was wrong and needed fixing when families came into treatment. Although all of the new leaders focused on social interaction theories of stability and change in the family system as a whole when explaining the etiology and locus of psychopathology, each emphasized the role of one or more aspects of internal psychological factors in both individual and family maladaptation. This period, in which new, competing schools of family therapy training and services were established, but in which little systematic evaluation occurred, has been characterized aptly, though perhaps too harshly, as the “battle of the brand names” (Hoffman, 1981).

One of the few second-generation family therapists to maintain a direct connection with treating mentally ill patients and their families was Carl Whitaker, who emerged as a leading figure first at Emory University in Atlanta and later in the Department of Psychiatry at the University of Wisconsin Medical School. His forte was not the construction of grand theories or the proposal of unique formulations of the central issues faced by families. His influence came through demonstrating his approach in large workshops and small, intense meetings of the movers and shakers of the family therapy world (Whitaker & Bateson, 1958). Although he focused on the systemic properties of the family, as a therapist Whitaker paid close attention to his own inner thoughts and feelings during the session and expressed them to the family. That is, he used psychodynamic notions of transference and countertransference in the therapy, primarily as a way of joining with clients at the same time that he disequilibrated them with cryptic but remarkably on-target remarks.

An offshoot of a more consistently psychodynamic family theory such as Ackerman's (1962) could be found at the Family Institute of Philadelphia led by Ivan Boszormenyi-Nagy and James Framo (1965; Framo, 1992). They developed what they called contextual family therapy, with an emphasis on adults coming to terms psychologically and in direct interaction with their parents as a way to repair distress at the individual, couple, and parent-child levels.

After leaving the Palo Alto group, Jay Haley worked with Minuchin in Philadelphia to develop structural family therapy, with a focus on the role of the therapist in changing the organization of family subsystems. Haley then started a new school of strategic therapy that focused on the family's behavioral efforts to solve problems in the here and now (Haley, 1976; Madanes, 1984). Haley delighted in a "paradoxical" approach, telling families, as they described their problems, that the problems were objectively insoluble. The central task of the therapist was to help families reframe or redefine their plight and prescribe a set of strategies that would overcome family homeostasis and facilitate change, including "prescribing the symptom," in which he would ask families to repeat a maladaptive pattern in order to bring it into the open and place it under conscious control.

One of the strongest international developments in family therapy occurred in Italy, where Mara Selvini Palazzoli, Luigi Boscolo, Guiliana Prata, and Gianfranco Cecchin became the "Milan associates" (Selvini Palazzoli, 1985; Selvini Palazzoli, Boscolo, Cecchin, & Prata, 1978). Staying close in theoretical orientation to the Palo Alto group (Bateson and colleagues), they focused on short-term intensive interventions focused on disrupting the deviant communication "games" by which severely disturbed families (with severe eating disorders, Schizophrenia) maintained a maladaptive homeostasis. Haley and the Milan associates focused on behavior but were not behaviorists, in the sense of direct teaching of communication rules, exchange of reinforcing behaviors, or consequences for unacceptable behavior.

A quite different offshoot of Bateson's ideas from the Palo Alto group was narrative therapy (M. White, 1986; M. White & Epston, 1990), which focuses on the idea that family narratives or stories are often impoverished in disturbed families; the task of the therapist, through talking, writing letters to clients, and having clients write new narratives, is to reframe and refashion these stories with new possibilities. Like many postmodern theories, narrative therapies place great emphasis on the meaning of words and the constructions that family

members place on their realities, each of which has its own validity or truth.

Feminist Critiques of Family Systems Theories

In 1978, Rachel Hare-Mustin issued an opening salvo in an ongoing feminist critique of family therapy, making the point that early versions of family systems theories made highly gender-stereotyped assumptions about what constitutes pathological and nonpathological functioning in families (Walters, Carter, Papp, & Silverstein, 1988). The early masters of family therapy, almost all men, had focused their interventions on reestablishing traditional roles in chaotic families, in part by encouraging fathers to take a more active, often patriarchal role. This work virtually ignored the issues associated with the changing of women's roles stimulated by the women's movement starting in the 1960s (Chodorow, 1989; Friedan, 1963; Greer, 1980). Judging by the fact that sharply worded feminist critiques continue to appear, these issues have not yet been resolved (Almeida, 1998; Bograd, 1991; Coleman & Ganong, 2004).

In addition to the issue of roles, feminist family therapists focused on power in relationships between men and women, advocating that therapists help families to buck the cultural trends in which men hold not only the purse strings but the power to make decisions about many aspects of life inside and outside the family (Silverstein & Goodrich, 2003). The implication was that a feminist therapeutic approach would alleviate depression in women and provide examples of a better balance of gender roles for both daughters and sons. In fact, the systematic research that we are aware of suggests that less traditional divisions of labor are related to more satisfied and less symptomatic partners (Blair & Hardesty, 1994; Huppe & Cyr, 1997), but to our knowledge, there have been no direct tests of these assumptions by examining whether therapy-induced changes in the balance of power within couples are associated with more positive outcomes for the partners or their children.

Family systems theories and feminist critiques were presented and argued in the 1970s and 1980s on the basis of clinical experience, training programs in each of the family therapy schools, detailed written case materials, and sharp exchanges at national gatherings of family therapists. There was little reliance on empirical studies in the family research literature. We wonder whether the fact that family therapy training was primarily conducted in free-standing institutions that were not connected with academic or hospital research settings widened the gap between developments in the fields of family therapy and family research.

The Family Risk Factor Approach: An Expanding Focus on Family Relationships in Accounting for Psychopathology

During the 1970s and 1980s, influenced by the active ferment in family systems theories and therapies, there was a rapid rise of interest in family research, in the study of both normal development and psychopathology. Before 1960, research interest in whole families was so low that fathers were virtually invisible in research on child development. Eleven years after the publication of the first version of the *Manual of Child Psychology* (Carmichael, 1954), Nash (1965) pointed out that “father” had not been included in the index. A number of researchers, who would later become prominent, published papers on the impact of father absence (Biller, 1968; Hetherington, 1966, 1972; Mischel, 1961), but it was not until the 1980s that a body of work emerged looking at how variations in fathers when they were present were related to children’s development (Bronstein & Cowan, 1988; Lamb, Pleck, Charnov, & Levine, 1987; Power & Parke, 1983). Although research interest in fathers has continued and grown (Tamis-LeMonda & Cabrera, 2002), most child psychopathology researchers continue to neglect fathers (Phares, 1992).

Just as “father absence” was the stimulus for early studies of fathers’ impact on their children, so the study of how the parents’ marriage affects children’s development was stimulated by studies of divorce in the early 1980s (Hetherington, Cox, & Cox, 1982; Wallerstein & Kelly, 1980). Over the following 2 decades, a wealth of evidence suggested that high, unresolved couple conflict is a risk factor for most dimensions of adaptation in children (academic achievement, externalizing, internalizing; Ablow, 2005; Cummings, Davies, & Campbell, 2000; Emery, 1999).

Research on the intergenerational transmission of disorders also increased. The belief that positive or negative patterns of family interaction are repeated across generations and function as an antecedent to many different diagnoses is supported by the results of behavioral genetic studies of twins and siblings (Gottesman, 1991), epidemiological studies of family records (Mednick, Cudeck, Griffith, Talovic, & Schulsinger, 1981), and longitudinal studies of nonclinical families (Caspi & Elder, 1988). In the 1970s and early 1980s, the risk factor approach attempted to identify one or at most two family domains associated with child psychopathology. Only later, as we shall see, did these models become more inclusive as they attempted to incorporate information from all of the family domains in Figure 14.1.

A New Wave of Researcher-Clinicians

From the 1970s to the present day, some academically based researcher-therapists, influenced by family systems theory, began to focus on interventions in family subsystems, which brought new concepts and techniques to therapies focused on either parent-child or couple relationships. If we examine where the interventions were targeted, we can infer the assumptions of each approach concerning risk factors or causes of psychopathology.

Parent-Child Focus

To help parents to deal with their highly aggressive sons, Gerald Patterson (1975) began developing behavioral treatments in which parents learned techniques of reinforcement, time-out, and social learning through imitation. Presumably, parental failure to establish adequate controls was seen as the source of children’s misbehavior. Seven years later, Patterson took a more systemic bidirectional approach in his theory of “coercive family processes” (G. R. Patterson, 1982). Observing mostly mothers and children in interaction, Patterson noted that when a child was aggressive and a parent responded ineffectively, the child escalated the aggression, the parent again responded ineffectively (e.g., by “nattering” instead of giving clear directions), and the child escalated again until the parent backed off, thus reinforcing high-level aggression on the part of the child. Still later, risk factor models from Patterson’s group expanded to include additional measures of individual personality and functioning (G. R. Patterson & Capaldi, 1991), cognitive-behavioral conceptions, including parents’ and children’s interpretations of events, and the role of both sibling and peer relationships in the control of aggression.

Carolyn Webster-Stratton (1984, 1994) developed a videotape program for parents of aggressive children that presents dramatized vignettes of effective and ineffective parenting. In contrast with a more didactic teaching orientation characteristic of many behavioral interventions, Webster-Stratton’s individual therapists or group leaders use the taped excerpts to elicit explorations and observations from the parents in an attempt to involve them actively in the process of adopting new strategies of discipline with their children.

A newer dimension of parent-child relationships has been investigated but not yet used in interventions. John Gottman (2001; Katz, Wilson, & Gottman, 1999) describes meta-emotion coaching as parental behavior that helps children deal with their feelings of sadness or anger. When par-

ents are able to help their children explore their negative feelings rather than criticize them or dismiss the feelings, the children show less externalizing or internalizing behavior. What makes this construct a candidate for therapeutic trial is the suggestion from correlational studies that positive meta-emotion coaching can protect children from the vicissitudes of marital conflict in the family.

Couples Focus

Neil Jacobson, Gayla Margolin, Andrew Christensen, and Donald Baucom, separately and together, developed treatments for couples in distress (Baucom, Epstein, Rankin, & Burnett, 1996; Christensen et al., 2004; Christensen, Jacobson, & Babcock, 1995; Jacobson & Margolin, 1979). Like Patterson, they began by developing behavioral interventions based on different versions of exchange theories (one partner gives positive reinforcements in response to positive reinforcements) and on direct didactic teaching of communication strategies (e.g., using “I” statements and avoiding mind reading and blaming). Then, as Patterson had, these researcher-clinicians all moved toward more cognitive-behavioral approaches with an emphasis on how each partner *interprets* his or her own and the partner’s behavior, or on such nonbehavioral concepts as the need for acceptance when partners have differences or reach impasses that cannot be resolved (Christensen & Jacobson, 2000).

Just as the early family systems theories could be divided into those with a behavioral emphasis on the transactions among family members and those with a psychodynamic emphasis on the individual in the system, the field of couples therapy encompassed both approaches to understanding trajectories of relationship health and maladaptation. Two theories of couples therapy based their assumptions on an intrapsychic view of how problems in the couple are generated, one stemming from the object relations theories of Melanie Klein (1932), the other from John Bowlby’s (1982, 1989) attachment theory. Theories based on Klein’s work focused more on the ways that partners who are frustrated and unsatisfied with their primary object relationship (with mother) project their unacknowledged and rejected aspects of themselves on their partner (Dicks, 1967; Mattinson & Sinclair, 1979). One partner’s anger that the other is frustrating his or her needs results in either anger or depression/withdrawal. In essence, as in Bowen’s family systems approach, the partners exist in a state of fusion or enmeshment in which each sees the other as an extension of himself or herself, and positive development through therapy involves a process of encouraging individuation. Object

relations theories of couple functioning were later expanded and systematized by David Scharff and Jill Scharff (D. E. Scharff & Scharff, 1991; J. S. Scharff & Bagnini, 2002).

A different intrapsychic approach to couples therapy, based on attachment theory, was developed by Clulow and his associates (Clulow, 1996; Clulow & Cudmore, 1985) at the Tavistock Marital Studies Institute in London. From this perspective, partners begin as separate individuals, and problems arise in the process of coming together. Anger or withdrawal in the couple relationship arises when individuals who are vulnerable because of insecure working models of attachment become threatened by fear of losing the relationship. One of the therapist’s main tasks is to understand the working models that each partner brings to the relationship and to provide a secure base in the therapy room that partners can use as a platform to analyze and revise their distorted working models. The goal is to help each partner begin to function as a secure base for the other.

The Current Couple and Family Systems Scene: Integrations

A number of textbooks and handbooks describing couples and family therapy (Gurman & Jacobson, 2002; Gurman & Kniskern, 1981, 1991; Jacobson & Gurman, 1995) have been published over the past 2 decades. A brief comparison of later volumes with earlier ones suggests a move toward theoretical integrations. Lebow (1997) summarized the trend with an influential article in *Family Process*, noting the different meanings of “integration.” Eclecticism is one alternative—the incorporation of disparate theoretical ideas and intervention techniques into family assessment and therapy. At another extreme is an integration that synthesizes disparate elements into a coherent theoretical model. Although some observers question whether this kind of integration is possible (e.g., Grunebaum, 1997), Lebow describes midlevel integrations—attempts by a theorist or therapist to give equal attention to *at least* two family domains (e.g., couple and parent-child) or levels of analysis (a subsystem and the whole family) or explanations of stability and change (biological, psychological, social or internal, external, interactive). Given the rich array of recent integrations, we are able to provide only a few examples.

Integration across Domains: Couple and Parent-Child

Behavioral interventions for parents of aggressive children have been remarkably successful (P. A. Cowan et al., 1998;

G. E. Miller & Prinz, 1990), at least in the short run. Nevertheless, when therapist-researchers looked at evidence that some children did not change whereas others improved but later reverted to baseline, several began to suspect that parenting changes were more difficult to achieve when the child's parents were engaged in high levels of conflict. Brody and Forehand (1985) added to their parenting intervention a new focus on coparenting *and* marital issues. In the Brody and Forehand study and another intervention evaluation by Dadds and his colleagues (Dadds, Sanders, Behrens, & James, 1987), a combined marital and parenting emphasis was more successful in reducing sons' problem behavior than a traditional parenting skills approach with mothers only. Webster-Stratton (1994) showed similar results in her recent work with couples whose children had behavior problems. These intervention results, as we have noted, provide evidence in support of the hypothesis that both marital and parent-child relationships play important roles in the development or maintenance of psychopathology in the child.

Integration across Domains and Levels of Analysis

By far, the majority of family theory integrations attempted to combine a focus on how psychological or biological processes of each individual play out in the transactions between partners or among family members.

Biological and Family Processes Until relatively recently, family theorists have acknowledged but generally ignored the fact that genetic factors play some role in individual psychopathology. Plomin and his colleagues (Hetherington, Reiss, & Plomin, 1994; Plomin, 2003) have made what seems like a paradoxical claim: that behavior genetic studies can be used to make the best case for the importance of family relationship risk factors in psychopathology. To begin with, these investigators depart from the usual practice of studying only one child in each family so that they can identify the contributions of both nature and nurture to variations among siblings in behavior and adaptation. Twin studies and adoption studies have been used for some time to make the case that there is a genetic component to Schizophrenia, Bipolar Disorder, depression, and many personality traits in nonclinical populations (Gottesman, Shields, & Meehl, 1972). Somehow, the focus on finding proof of genetic risk factors obscured an obvious point: Even in twins who are genetically identical, the probability that both will be diagnosed with Schizophrenia is, at most, about 50% to 60%. This means that there must be some nongenetic factors that account for sibling differences. The contribution

of Plomin and his colleagues was to calculate a heritability index for each outcome under investigation (with perfect heritability $[h] = 1.0$) and then to search for *two* sources to explain the remaining variance ($1-h$): shared environmental similarities that tend to make siblings similar (e.g., being treated similarly by parents), and nonshared environmental conditions that tend to make siblings dissimilar (e.g., being treated differently by parents). Using data from sophisticated studies of identical twins, fraternal twins, and siblings in both adoptee and nonadoptee families, these investigators interpret their results as showing that once genetic factors are accounted for, much of the remaining variation in severe psychopathology comes from nonshared family factors—conditions that make for differences between siblings. Both shared and nonshared effects are aspects of family processes that are consistent with a social external view of adaptation.

Space precludes an elaborate analysis of the nonshared approach. It has been criticized on the grounds that heritability coefficients overestimate the contribution of genetic factors to psychopathology because the estimates are specific to the population they are assessing, and that restrictions in variation within each study necessarily inflate the size of the heritability coefficient (Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000). More recent critiques also suggest that the contributions of nonshared environments have been overestimated at the expense of shared environmental effects (Spinath, 2004). Nevertheless, in our view, Plomin and his colleagues have provided solid evidence supporting the hypothesis of an interaction of genetics and family processes in a number of *DSM* disorders (see discussion later in chapter).

Intrapersonal Cognitive Processes and Interpersonal Behavior Consistent with the tenets of the cognitive-behavioral individual therapies growing in importance during the 1970s, some researcher-clinicians added to their analysis of couple communication patterns new ideas about how one partner's interpretation of the other's behavior could affect subsequent interactions between them. Attribution theories of couple interaction (Grych et al., 2000) pinpoint negative interpretations of the motivation behind a family member's behavior (e.g., "You did that just to frustrate me") as a risk factor for increased interpersonal conflict. In another perspective on the importance of interpretation, Christensen and Jacobson (2000) show that behavior that violates the couple relationship (e.g., adultery) is not necessarily corrosive in the long term unless one partner refuses to forgive the transgression.

Emotion Processes, Cognition, and Interpersonal Behavior In laboratory research, J. M. Gottman and Levenson (1986; Levenson & Gottman, 1983) first identified behavioral patterns (escalating negative affect) and physiological patterns (men's tendency to stonewall in verbal communication during a discussion of a marital disagreement, though their physiological arousal was high) as risk factors for couple dissatisfaction and distress. That is, both dysregulation of internal emotional arousal and dysregulation of emotional expression as partners interact are important ingredients of couple adaptation. Applying these findings to therapy (J. M. Gottman, Ryan, Carrere, & Erley, 2002), Gottman and his colleagues also emphasize the importance of each partner's aspirations and dreams and the negative consequences for relationships when one or both partners fear disappointment that their life dreams will not be realized in this relationship. Behavioral, affective, and cognitive integrations are also featured in Christensen and Jacobsen's integrative therapy (Christensen et al., 2004).

Attachment Processes and Interpersonal Behavior Emotionally focused couple therapy (EFT) was developed by Leslie Greenberg and Susan Johnson (1988) and later expanded by S. M. Johnson (2004). EFT represented a reaction to the behavioral approach. Based on observation of couples therapy tapes, these clinicians concluded that too much attention was given to cognition, problem-solving, and behavioral strategies, and not enough to emotional moments and attachment issues. Their primary hypothesis was that distress in couple relationships is caused by the fact that when differences arise, one or both partners may be vulnerable to the threat of separation and loss; one or both then react emotionally by dismissing, denying, and defending or with high levels of anger, with either alternative driving the partners further apart. Once insecurities about the relationship are aroused, Johnson argues, they are maintained by the manner in which the partners interact. Thus, explanations of psychopathology and attempts to treat couples are based on a psychological and social analysis that posits an interaction of internal and external contributions to individual distress and relationship disruption. Their retention of a behavioral communication focus in addition to the attachment focus makes their therapy quite different from the attachment-based therapy described by Clulow (1996). The attempt to integrate attachment and behavioral theories has also been a central feature of Gurman's (2002) brief integrative therapy and Christensen and Jacobson's integrative therapy (Christensen et al., 2004).

Why Integrations Are Needed

From the perspective of twenty-first-century theories of psychopathology, the need for integrations of theories explaining the development of psychopathology seems obvious. Although traditional individual and family therapies have been shown to be effective when participant are compared with those in control groups (Shadish, Ragsdale, Glaser, & Montgomery, 1995; Weisz, Weiss, Han, & Granger, 1995), it is clear that these therapies do not provide help for substantial numbers of people. On both conceptual and empirical grounds, it is easy to see that no single family domain can possibly explain how some families at similarly high levels of risk follow trajectories toward different kinds of psychopathology, and others move toward adequate or even superior levels of adaptation. Similarly, in a time when biopsychosocial models (Engel, 1980) are becoming widely accepted (Whitbourne, 2005), it does not seem reasonable to limit one's view to a single level of analysis—biological, psychological, *or* social—to account for the links between risks and outcomes. It seems futile to maintain either an internal or an external explanation of stability and change when there is so much evidence of protective and vulnerability effects; whether external risk factors eventuate in psychopathology depends on whether internal factors protect individuals from harm or represent vulnerabilities that make them particularly susceptible to greater distress. As Cicchetti and Dawson (2002, p. 418) wrote, "Progress toward a process-level understanding of mental disorder will require research designs and strategies that call for the simultaneous assessment of multiple domains of variables both within and outside the developing person."

Our six-domain family risk model (Figure 14.1) and the nine-cell matrix explaining stability and change (Figure 14.2) can be thought of as checklists that delineate possibilities from which integrative family theories have made choices. For example, couples therapies have begun to include individual, couple, parent-child, and three-generations perspectives on the relationship, but except for feminist family theorists, they have paid relatively little attention to stresses and supports from outside the nuclear family (see Gurman & Jacobson, 2002, for descriptions of many different approaches to couples therapy). Family therapies, especially those treating delinquent or drug-abusing adolescents, have begun to address outside-the-family issues with peers, schools, and neighborhoods (e.g., Liddle & Hogue, 2000). Conceptualizations of stability and change in family theories now regularly include

internal and external psychological and social explanations, but they pay attention to biological levels of analysis primarily when psychoactive drugs are part of the treatment.

This both/and rather than either/or approach to integrations argues for the need to integrate family systems and family risk factors theories of psychopathology. Each has important limitations that the other can address. Rosenblatt (1994) provides a cogent analysis and critique of the metaphors used by family systems theorists and shows how each of the central constructs is simultaneously enlightening and limiting. For example, the assumption that families as whole systems have properties that are independent of the parts leads to the useful idea that it is normal and expectable for *systems* to resist the disequilibrium associated with change and transition. At the same time, focusing on the system ignores the fact that specific strengths and vulnerabilities of individual family members often have a marked impact on the functioning of individuals, dyads, and the system as a whole. Conversely, the family factors approach addresses the contributions of individual family members and dyads to psychopathology and adaptation, but usually fails to consider the properties of the system as a whole that protect individuals and relationships from risks in specific domains, or amplify difficulties in one domain to the point where they spill over into other domains of family life.

DEVELOPMENTAL PSYCHOPATHOLOGY IN NONCLINICAL FAMILIES

Before we examine evidence regarding family systems and family risk models of psychopathology in individuals already diagnosed by the mental health system and involved in treatment, we want to show how these models are relevant to understanding adaptation in nonclinical families. These families are not selected for studies because they are without problems, but because they have not been identified by the mental health delivery system as in need of treatment, and they have not volunteered to participate in a study because they have identified themselves or their families as in need of psychological help. Typically, they are families recruited to a study of marital relationships, parent-child relationships, normative family transitions, and the like. Nevertheless, as we know from developmental psychopathology research, some of the individuals in these families are suffering significant psychological distress, and a subset meet the criteria for one or more diagnosable disorders. Consistent with the tenets of developmental

psychopathology, we believe that research on this population is essential to the understanding of who develops psychological problems and who does not.

Family Systems Assessments of Normal Families

Several systems-level assessment approaches have been developed to allow researchers to arrive at a picture of how the family as a whole functions. Although they have all been developed by clinicians and mostly been used in the study of families with already diagnosed problems, they were all created explicitly for use with nonclinical families, and each explicitly focuses on strengths as well as weaknesses in both family structure and family process. The McMaster model of family functioning (Epstein, Ryan, Bishop, Miller, & Keitner, 2003) has led to a multi-method assessment of family problem solving, communication, family roles, affective responses and involvement, and behavioral control. Well-functioning families are able to solve problems, communicate directly and effectively, operate with a clear sense of who does what, express feelings in a context of empathy, and operate inside and outside the family in an appropriately controlled but not rigid way. The assessment includes an extensive interview of the whole family (the McMaster Structured Interview of Family Functioning; Bishop et al., 2000) and a questionnaire administered to each family member (Epstein, Baldwin, & Bishop, 1983). The assessment has been used in clinical settings in a few studies conducted in the 1970s and 1980s (see Epstein et al., 2003) and more recently by the Providence Family Study (Dickstein et al., 1998). Results demonstrate the interconnection among various levels of family assessment in families with a mentally ill parent (see discussion later in chapter).

Like the McMaster model, the Beavers systems model (Beavers & Hampson, 2003; earlier called the Beavers-Timberlawn model) uses a combination of observational ratings and self-reports to describe the family system (the Interactional Competence Scale, the Beavers Interactional Style Scales, and the Self-Report Family Inventory; Beavers & Hampson, 1990). Unlike the McMaster model, the Beavers system uses classical constructs from structural (Minuchin, 1974) and strategic (Haley, 1990) family therapy such as boundaries, power, autonomy, communication, and problem solving to classify families along two orthogonal dimensions. The first dimension places families along a competence continuum from severely dysfunctional, borderline, and midrange, through adequate, healthy, and optimal. The second dimension describes families in terms of members' tendency to turn inward toward each other or outward to-

ward the world to get their needs met. The scales have been used successfully in evaluations of marital therapy and family therapy (Hampson & Beavers, 1996; Hampson, Prince, & Beavers, 1999). The results demonstrate a linear relationship between a family's level of competence and therapy outcomes, in which more competent families benefited more from treatment. The authors also discuss the types of therapists who were most helpful to families at the low and midranges of the scale.

Reiss and Oliveri (Reiss, 1981; Reiss & Oliveri, 1983) observed family members communicating with each other as they attempted to solve puzzle-like problems, and used both behavior and perceptions of the members to describe a "family paradigm": the orientation of the family unit to each other and to the outside world. They describe three uncorrelated dimensions: (1) Configuration refers to the ability of family members working as a group to recognize patterns; (2) coordination refers to their ability to cooperate and integrate their actions; and (3) delayed closure reflects the openness of the family to new information. Empirical evidence reveals that high scores on all of these dimensions are correlated with successful coping with physical illness and alcoholism (Reiss, Costell, Jones, & Berkman, 1980; Reiss, Gonzalez, & Kramer, 1986; Reiss & Oliveri, 1983). Speculative extensions suggest how these dimensions could be related to various categories of mental illness (Reiss & Klein, 1987).

The circumplex model of marital and family systems (Olson & Gorall, 2003) uses a single self-report instrument, the Family Adaptability and Cohesion Evaluation Scale (FACES), now in its fourth revision (FACES IV; Franklin, Streeter, & Springer, 2001). Questions cover two bipolar dimensions in which optimal functioning lies at the midpoint of a curvilinear dimension, and maladaptive functioning at each end of the curve. Relationships can range from disconnected (separateness, low closeness, low loyalty, high independence) through connected (balanced) to overly connected (too much togetherness, excessive loyalty demands, high dependency). Relationships can also range from inflexible (rigid, authoritarian, unchanging, strict discipline) through flexible, to overly flexible (constant change, lack of leadership, dramatic role shifts, erratic discipline). Olson and Gorall note that earlier versions of FACES failed to validate the curvilinear hypothesis because there were not enough items on the enmeshed and high-change ends of the continua, but that there are promising indications that FACES IV shows the expected curvilinearity. About 10 studies find that this self-report measure correlates with observation (Kouneski, 2001). Space precludes a review of the many investigations that

have used this instrument, primarily in studies of nonclinical families.

There are other self-report measures that attempt to take a whole-system perspective on the family, including the Family Environment Scale (Moos, 1974), with dimensions of cohesion, organization, and family growth orientation, and the Family Assessment Measure (Skinner, Steinhauer, & Sitarenios, 2000; Steinhauer, Santa-Barbara, & Skinner, 1984), with both whole-family and dyadic descriptions provided by each family member. Like FACES, but with less extensive research, both of these instruments demonstrate that they differentiate between well-functioning families and families with a member who has been diagnosed with a clinical disorder.

Various authors have attempted to compare these whole-family measurement systems (e.g., Grotevant & Carlson, 1989; Hampson & Beavers, 2004), but none that we are aware of provides empirical studies of intercorrelation or differential connections with adaptive and maladaptive outcomes. The McMaster and Beavers models include both observers' and family members' perspectives, whereas the circumplex model relies on an inner view of family life from the perspective of each family member. All these models attempt to assess some level of cohesion and boundaries—whether family members turn toward each other or focus their attention outside the family—and all attempt to ascertain whether the family has a stable, flexible organization for solving problems and communicating feelings.

What remains to be worked out with these and all other measures of family functioning is that they present two different perspectives, what Reiss (1992) calls the represented and practicing family, with representations derived from family members' self-reports and descriptions of family practices derived from observers. We do not yet have very clear ideas about how well these perspectives fit together, how well they should be expected to correspond, or what the implications may be for family adaptation when family members' perceptions fail to correspond with observers' descriptions of family interaction.

Risk Factors in Family Transitions

In contrast with times of relative quiescence when family coping processes may not be as visible to outsiders, family transitions bring new challenges that call for new resources. At these times, the characteristic strengths and vulnerabilities of family members and their relationships can be seen in sharper relief (P. A. Cowan & Cowan, 2003). Even more relevant to the study of developmental psychopathology, the disequilibrium associated with making a life

transition can lead either to higher levels of adaptation or to lower levels of functioning that place the individual or family further along the path toward maladaptation (McCubbin & Patterson, 1983). Our definition of transition does not include any of the innumerable small shifts in family members or in the system as a whole, but rather changes that involve a qualitative shift in each individuals' view of self and the world, social roles, and central relationships (P. A. Cowan, 1991).

The Couple's Transition to Parenthood and the First Child's Transition to School

There are two main ways to study families in transition—by following them over time and charting correlations between coping strategies and outcomes, and in experimental designs (interventions with random assignments to conditions) that evaluate whether intervention-produced skills make a difference in how transitions are managed.

Correlational Studies. Nonnormative life transitions are those triggered by suddenly occurring challenges that are either unexpected, such as earthquakes, or unexpected at a given time, such as serious illness. It is obvious that these transitions might increase the risks of disequilibrium and actual distress. By contrast, normative transitions are expectable and experienced by the majority of individuals or families in a given culture (e.g., emergence into adolescence or adulthood, entering the paid workforce, establishing an intimate relationship, cohabitation or marriage, becoming parents). Often, though not always, these transitions are actively sought and welcomed when they occur. Nevertheless, it has become clear that even when the transition brings great joy, the individual and the family is at risk for increased levels of disequilibrium and/or stress. The transition to parenthood and the child's transition to school are two cases in point in the early years of family life.

We and a number of others have described longitudinal studies that reveal the challenges faced by partners becoming parents (Belsky & Kelly, 1994; C. P. Cowan & Cowan, 2000; Cox, Paley, Payne, & Burchinal, 1999; Heinicke, 2002; Shapiro, Gottman, & Carrere, 2000). As men and women attempt to cope with the demands of caring for a small and unpredictable infant under conditions of uncertainty and sleep deprivation, they experience changes in each of the central domains of the family. They must incorporate their new identity as a parent. They take on more traditional role arrangements as couples than they expected. They each begin to forge a new relationship with their child, at the same time that they must reorganize their relationships with their parents and kin. In modern cou-

ples, both partners struggle to balance the demands of work and family responsibilities, maintain outside sources of support, and minimize outside sources of stress (C. P. Cowan & Cowan, 2000).

A review of more than 25 longitudinal studies of partners becoming parents (C. P. Cowan & Cowan, 1995) published a decade ago shows that during this period, couple conflict increases and, for the vast majority, marital satisfaction declines. A more recent overview comes to the same conclusion (Bradbury & Karney, 2004). In a second study of families whose first child was making the transition to elementary school (Cowan et al., 2005), we found that, marital satisfaction continued to decline, despite several positive changes in parents' lives during the transition-to-school period.

For couples with relatively positive relationships who become parents or see their first child off to elementary school, this decline in marital satisfaction may not prove to be problematic. As in other transitions, couples at the positive end of the distribution tend to maintain their position over time (Belsky & Pensky, 1988). Unfortunately, those with quite negative views of the relationship show a further decline over time, which may have serious consequences¹ because at the low end of the distribution, distressed marriages constitute a primary risk factor for children's adaptation (Cummings et al., 2000; Emery, 1999).

Studies of the transition to parenthood and the early child-rearing years confirm that distressed couple relationships are important to understand, but they also make it clear that a troubled marriage is only one of the family risk factors that predict children's academic, social, and emotional problems. There is now ample evidence that the other four domains in our family risk model explain significant amounts of variation in children's development. Parents' depression, mental illness, and other indicators of psychopathology place children at risk for behavior problems and other cognitive and emotional difficulties (Campbell, Cohn, & Meyers, 1995; Fendrich, Warner, & Weissman, 1990; Nolen-Hoeksema, Wolfson, Mumme, & Guskin, 1995; Sameroff, Seifer, & Zax, 1982). The behavior of each parent with the child, of course, explains substantial variance in children's adaptation (P. A. Cowan et al., 1998; Maccoby & Martin, 1983; Parke & Buriel, 1998). The intergenerational transmission of parent-child relationship quality from grandparents to parents to children is the rule rather than the exception (van Ijzendoorn, 1992). Parents'

¹ Later in the chapter we address whether the correlations actually represent causal influences of marital quality on children's adaptation.

work-related stress, economic stress, and other stresses from outside the nuclear family also function as risk factors for the development of psychopathology in their children (Conger, Ge, Elder, & Lorenz, 1994).

How do all of these risk factors combine to explain variations in children's adaptation? Static snapshots using multiple regression techniques suggest that family risk factors combine additively to predict children's outcomes. The more risk factors present (Sameroff, Seifer, Baldwin, & Baldwin, 1993), and the more intense the risk (Cummings & Davies, 1994), the more severe the child's problems are likely to be. In our own research (P. A. Cowan & Cowan, 2005), we used multiple regressions to analyze risk factors from each of the five family domains in our conceptual model. Results indicate that data from each domain contributed *unique* variance to the prediction of the children's achievement, externalizing problems, and internalizing problems in first grade.

Multiple regressions simply add risk predictors together but do not examine the interplay among the family factors—what we call the “dynamics” of family relationships. Structural equation models (path models) remedy this defect. In statistical terms, the connections among family domains can be direct or indirect. Depression in one or both parents may directly predict disruptions in parent-child relationships (Campbell et al., 1995; Hops, 1992). Or, it may be that depression in parents is associated with high marital conflict, and marital conflict is associated with more negative, less effective parent-child relationships (N. B. Miller, Cowan, Cowan, Hetherington, & Clingempeel, 1993).

Preventive Interventions. There are four central justifications for considering preventive intervention programs for nonclinical couples as they make the transition to parenthood and as their first child makes the transition to school. First, with a divorce rate between 40% and 50%, it is clear that marriages are at risk. If a physical health problem had a 40% probability of occurring in a population, it would be clear that steps would have to be taken to address it. Second, risk indices in other domains of family life are also high. For example, in both our transition to parenthood and transition to school studies, with different families in each, about 33% of the men and women scored above the clinical cutoff on a widely used depression symptom scale (C. P. Cowan & Cowan, 2000). Third, we found a considerable proportion of the parents in our studies in distress as a couple, and, as we have seen, parents' marital distress is a risk factor for psychopathology in the children. Early intervention, before these problems become exacerbated, makes good sense. Fourth, if randomly assigned interventions

show effects on parent-child or marital relationship quality, investigators can draw conclusions about the causal impact of family relationships on children's adaptation.

Our randomized clinical trial of a 24-week couples group for couples becoming parents, led by a male-female team of trained mental health professionals (C. P. Cowan & Cowan, 2000), and a similar trial of a 16-week couples group for parents whose first child was entering kindergarten (C. P. Cowan, Cowan, & Heming, 2005), showed statistically significant effects. Compared with controls, parents from the couples groups showed much smaller declines in marital satisfaction in the years following the transition. The impact of the transition to parenthood group, conducted in the months surrounding the transition, lasted at least until the children were in their 1st year of elementary school (Schulz, Cowan, & Cowan, *in press*), almost 6 years after the intervention. Preliminary analyses show that the published positive results of the transition to school intervention from prekindergarten to first grade (C. P. Cowan et al., 2005) were also found in subsequent follow-ups at fourth grade, almost 6 years after that intervention.

An intervention for low-income mothers during the transition to parenthood by Heinicke and colleagues (Heinicke et al., 1999; Heinicke, Rineman, Ponce, & Guthrie, 2001) produced positive effects on mothers' self-reported symptoms and observed interactions with their infants. Another intervention study for expectant couples (Shapiro & Gottman, 2003) found that, compared with couples in a no-treatment control condition, couples becoming parents who participated in a 2-day psychoeducational workshop were more satisfied with their marriage; the wives reported fewer symptoms of depression and were observed to be less hostile during a couple problem-solving discussion. Two other couple-focused interventions for expectant parents are now in the process of being evaluated (John Gottman, personal communication, October, 2004; Jordan, Stanley, & Markman, 2003).

In our intervention conducted in the year before the first child entered kindergarten (C. P. Cowan et al., 2005), there were two variations: The couples groups that emphasized parenting issues resulted in a positive change in parenting but no change in marital interaction; the couples groups that emphasized marital issues resulted in a reduction in conflict between the parents during a family interaction task, as well as increases in parents' warmth and provision of structure with the child. In comparison with children whose parents were in the control condition, children whose parents participated in the couples groups emphasizing marital issues had higher tested achievement scores in kindergarten and lower levels of externalizing and peer

problems in first grade. Finally, there were links between intervention-induced change and child outcomes. It appears that reductions in marital conflict and increases in effective parenting both played a causal role in children's academic and social adaptation to the early years of elementary school.

Divorce and Remarriage

Like studies of the transition to parenthood and the transition to school, examinations of the potential impact of divorce on children have been conducted using both correlational and experimental designs.

Correlational Studies. Some time ago, we were intrigued to read an early account of the changes in families following divorce by Hetherington and Camara (1984). If the reader substituted the words "transition to parenthood" for "divorce," the description would be consistent with the literature on new parents and make perfect sense. Structural equation models and regression equations describing risk factors in family dissolution and reconstitution also bear a remarkable resemblance to those obtained in studies of family formation. Parental depression following divorce is a risk factor for children (Hetherington, 1999). There is ample evidence that children fare well in families in which couples have good marriages or "good divorces" (Ahrons, 2004), but not when the relationship between their parents is full of unresolved conflict (Arendell, 1997b; Cummings & Davies, 1994; J. R. Johnston, 1994). As it does in intact families, unresolved conflict in divorced families places parent-child relationships at risk, not only in terms of relationship quality (Tein, Sandler, MacKinnon, & Wolchik, 2004), but also in terms of fathers' involvement in the daily life of the child, which tends to decrease when the parents are at war (Braver & Griffin, 2000; Carlson & McLanahan, 2002a; Coley & Chase-Lansdale, 1999). Divorce has an intergenerational aspect, in that adult children of divorce are more likely to end their own marriage (Amato, 2000). And, as it does in intact families (Conger, Elder, Lorenz, Simons, & Whitbeck, 1994; Mistry, Vandewater, Huston, & McLoyd, 2002), poverty associated with divorce, especially for women, tends to have its effects on children by disrupting family relationships, which is followed by both academic and social difficulties for the children (Hetherington & Kelly, 2002). When income level is statistically controlled, many of the associations between family structure and children's problematic outcome are reduced (Amato, 2001; Furstenberg & Teitler, 1994). That is, the negative effects of divorce come in part from the conse-

quences associated with poverty, rather than directly from family dissolution.

Preventive Interventions. Wolchik and her colleagues (Tein et al., 2004; Wolchik et al., 2002; Wolchik, West, Westover, & Sandler, 1993) tested two versions of a preventive intervention, one for divorced mothers and one for divorced mothers and their 9- to 12-year-old daughters. Both programs provided 11 weekly sessions co-led by two master's level clinicians, who focused on improving mother-child relationship quality, teaching more effective discipline techniques, increasing fathers' access to the child, and reducing interparental conflict. Follow-ups occurred immediately and 3 months, 6 months, and 6 years after the intervention. The two programs had similar effects. An earlier evaluation at the immediate and 6-month posttests indicated that the reduction in children's externalizing behaviors was associated with reductions in the hypothesized risk variables: ineffective parental discipline and negative mother-child relationships. Neither program affected the young adolescents' internalizing.

Dilemmas in Assessing the Impact of Family Life Transitions

Interventions focused on the transition to parenthood, to school, and to divorce have a great deal to contribute to discussions of whether family processes are causally related to children's outcomes. But the question of whether the transition itself can be interpreted as causing distress in family members is difficult to answer. Several studies that compare childless couples with couples becoming parents show that couples without children also experience a decline in marital satisfaction over time (e.g., Clements & Markman, 1996; S. M. McHale & Huston, 1985; L. K. White & Booth, 1985). All of these studies began with engaged couples who were young and followed them for short periods of time. By contrast, our comparison of couples having children with a sample of couples not yet decided about having children, followed over 6 years, showed that the decline in marital satisfaction was steeper for the parents than for the couples who remained childless (Schulz et al., in press). A similar comparative study of couples with a wide range of age found the same trends (Shapiro et al., 2000). These findings do not prove that the transition to parenthood was the causal agent, because it is possible that selection factors that determined who decided to have children and who did not were operating to produce the differences.

Similar problems exist in making claims about the *impact* of divorce on children. Almost all studies of this topic have three serious flaws:

1. Until recently, investigations began only *after* the parents separated or divorced. It is reasonable to assume that there may be a selection factor in operation. Children of parents who eventually divorce have been exposed to the parents' relationship difficulty prior to the divorce (Block, Block, & Gjerde, 1989; Cherlin, Furstenberg, Chase-Lansdale, & Kiernan, 1991). It may be the cumulative effects of predivorce relationships rather than divorce itself that is responsible for difficulties that some children experience after their parents have separated.
2. Almost all studies compare children of divorced and non-divorced families, without considering the potentially detrimental impact on children of living with high-conflict parents who stay together (see earlier discussion).
3. A third design flaw, ubiquitous in current research, results from the undifferentiated research question "Does divorce hurt children—yes or no?" We agree with Amato (2000, p. 1282), who suggests a more differentiated approach: "Divorce benefits some individuals, leads others to experience temporary decrements in well-being, and forces others on a downward trajectory from which they might never recover fully. Understanding the contingencies under which divorce leads to these diverse outcomes is a priority for future research."

Family Systems and Family Transitions

Our description of the transition to parenthood, like our description of divorce, has been formulated within the framework of family risk models that provide accounts of how change in various domains of family life affect the adaptation of the children. There are very few examples of research on family transitions that adopt a family systems perspective. A welcome exception is the work of James McHale (J. P. McHale et al., 2004; J. P. McHale & Rasmussen, 1998), who explores the interconnections among individual factors (e.g., child temperament, adult symptomatology), dyadic factors (e.g., the coparenting relationship), and triadic, whole-family perspectives on the transition to parenthood and early family functioning. The whole-family measures in McHale's studies are adapted from the work of Fivaz-Depeursinge (Fivaz-Depeursinge & Corboz-Warnery, 1999), who created the Lausanne triogue play procedure. This observation paradigm involves videotaping a mother and father together first taking turns and then working together to engage the attention of their infant, who is seated in an orthopedic car seat that the parents can swivel as they attempt to direct the infant's attention. Although some of the coding of this interaction involves a focus on individuals and dyads, combined scores represent *family* levels of coop-

eration, competition, and warmth. Some dyadic coparenting measures are derived from observation, and others are derived from discrepancies between the parents' self-reports. The research shows that parents' prenatal marital quality sets the stage for postnatal coparenting quality and the atmosphere in the family as a whole. Furthermore, high prenatal marital quality kept the parents from responding negatively when their 3-month-old babies were irritable.

Despite the relative absence of systematic studies of family transitions using a systems perspective, there have been detailed clinical descriptions of families from a systems point of view of families undergoing normative transitions such as the transition to adolescence or marriage, and by nonnormative changes resulting from illness, death of family members (e.g., Boss, 1999), and natural catastrophes (e.g., Carter & McGoldrick, 2005).

Overall similarities among systemic discussions of quite different life changes reveal that a transition in even one family member creates disequilibrium in the system as a whole. Whether families can use the period of transition as a catalyst for growth, or whether they succumb to passivity or depression, depends in part on a combination of family system competencies, the stressfulness of the transition, and the psychological, social, and financial resources of the family to meet the demands for change imposed by the transition. All of these formulations bear some resemblance to the ABC-X model initially proposed by life span sociologist Reuben Hill (1949), later expanded by Boss (Boss & Mulligan, 2003) and McCubbin (McCubbin, Thompson, Thompson, & Futrell, 1999), in which the outcome of any life stressor (X) depends on environmental demands (A), family resources (B), and appraisals of the meaning of the stressor (C).

Our conclusion is not that the family disequilibrium surrounding divorce is exactly the same as disruptions that follow when partners become parents or the first child makes the transition to school, but rather that similar risk factor models can be applied to these and other family life transitions. A great deal more research will be needed to determine the precise arrangements of the patterns of prediction, and which variables may play stronger or weaker roles in different transitions at different times.

DEVELOPMENTAL PSYCHOPATHOLOGY IN FAMILIES IN WHICH AT LEAST ONE MEMBER HAS BEEN CLINICALLY DIAGNOSED

In the previous section, we explored how multidomain family models account for variations in adaptation in

nonclinical families. Here we show that similar principles apply to the explanation of clinically diagnosed psychopathology in families in which at least one of the members has received a diagnosis. Our strategy here is to focus selectively on a number of issues that illustrate current thinking about the linkage between families and psychopathology. We begin with a discussion of the pitfalls involved in validating family systems theories and then discuss the evidence for the family factors approach.

Difficulties in Validating Family Systems Theories of Psychopathology

Two kinds of evidence are cited as supportive of family systems assumptions about the etiology of various psychopathologies. First, there is considerable evidence that, as a group, families with a clinically diagnosed member differ from nonclinical families in many of the ways that family systems theorists have hypothesized (e.g., Wenar & Kerig, 2000). Second, there is also considerable evidence that treatments of families using variations of conjoint family therapy have a significant positive effect when compared with randomly selected no-treatment controls (see discussion that follows). Our task here is to explore the conclusions we can draw from these facts.

Correlational Designs

Research that compares whole-system structures or processes in families with or without a member with a specific diagnosis is a necessary first step in validating family systems theories of psychopathology. The number of studies that fit this description is not large, but the results are consistent with the theories. For example, families with a member diagnosed with Schizophrenia showed more instances of communication deviance (Singer & Wynne, 1965b) than comparable families without a member who fits that diagnostic category. Even more important for the purposes of establishing specific links between family processes and Schizophrenia is the finding that these families also produced more disordered communication responses than families whose members had other diagnoses. Another set of studies investigated the construct of expressed emotion (EE) by asking relatives of an adult hospitalized patient diagnosed with Schizophrenia or Bipolar Disorder to talk into a tape recorder for 5 minutes to describe the patient. Family members coded as high in EE make more hostile, critical, or emotionally overinvolved remarks than family members low in EE. A number of studies show that relatives of diagnosed patients are much more likely to have high EE scores than relatives of nonpatients (Bebbington & Kuipers, 1994).

Except for families with a member diagnosed with Schizophrenia or Bipolar Disorder, it is rare to find studies that show family-level differences between diagnosed and nondiagnosed families. Shaw and his colleagues (Shaw, Criss, Schonberg, & Beck, 2004) cite several studies showing that hierarchical parent-child boundaries are either too rigid or too diffuse in families of children with ADHD or general emotional difficulties, but note that previous to their own, there have been no studies that investigate the origins of hierarchical boundary differences among families. These authors assessed families at high risk by virtue of poverty when the child was a toddler and followed up with assessments at age 10. Path models revealed direct links between early parent-child relationship difficulties and later vague or enmeshed boundaries reported by the mothers. Furthermore, parental adjustment, child temperament, marital difficulties, and ecological disadvantage (low education and income, dangerous neighborhood) were all indirectly linked with inadequate boundaries, which, in turn, were related to conduct problems as reported by both the mothers and the children at age 10 and 11. Boundary disturbances have also been found to differentiate between families without a diagnosed child and families with a 6- to 10-year-old with ADHD or depression, even after controlling for the presence of maternal depression (Jacobvitz, Hazen, Curran, & Hitchens, 2004). As predicted, boys in enmeshed families more often developed ADHD, whereas girls in similar families were more likely to develop depression. Taken together, these studies begin to raise important questions about why boundary disturbances are associated with different diagnostic outcomes in different families.

This first step—establishing differences between families with and without a diagnosed member—is necessary but far from sufficient to validate family systems theories. Almost all of these studies involve single time assessments and therefore employ the logic of correlation, even when the data are presented in the form of t-tests or analysis of variance (Shaw et al., 2004, is a welcome exception). Even if, for example, the chances of deviant communication are greater in families with a member with Schizophrenia than in families without a member in this diagnostic category, we do not know whether the deviant communication causes Schizophrenia, or the diagnosed member creates conditions that lead to deviant communication, or whether both result from a direct influence of a third variable such as underlying genetic vulnerability. These objections are not easily overcome.

Intervention Designs

Although intervention designs have some advantages in determining sequences and directions of effects, they are not

without problems of their own in the quest to validate family systems theories of psychopathology. It is difficult to find examples of systematic evaluations of family systems interventions, in part because investigators are often vague about what they mean by *family* treatment. Couple and family interventions are typically mixed together in research reviews and meta-analyses (Baucom, Shoham, Mueser, Daiuto, & Stickle, 1998; Shadish et al., 1995; Sprenkle, 2002). Existing examples show that, in studies using a randomized clinical trial design, conjoint family treatment produces more positive outcomes in families with members diagnosed with Schizophrenia, Conduct Disorder, or substance abuse than some form of low-dose treatment or no treatment (e.g., Diamond, Serrano, Dickey, & Sonis, 1998). A closer look suggests that, although these studies allow us to conclude that a given treatment was effective, they rarely provide direct validation for the family systems theories on which they are based. First, as we noted in the discussion of the nine-cell matrix of theories of stability and change, the demonstration that psychopathology diagnosed in a family member can be treated successfully in conjoint family therapy does not prove that family factors were the cause of the problems. What they do illustrate, and this is no small matter, is that family relationships *may* play a role in both stability and change in individual developmental pathways.

Second, what is missing from most family-based intervention studies is a demonstration not only that the treatment was effective, but also that the impact can reasonably be attributed to the *family* aspects of the treatment. This demonstration can occur by employing a research design that compares the outcomes of (1) conjoint family treatments for a given disorder with (2) treatments that use a family systems perspective, but not a conjoint treatment setting, and with (3) treatment of similar identified patients using a more traditional individually focused theoretical paradigm. We acknowledge that most therapeutic intervention studies do not compare *two* intervention groups with a control, but that is what is needed as a beginning step to examine whether the active ingredient in family systems-oriented therapy is in fact a change in the structure and process of the family system.

Some progress toward establishing family mechanisms involved in treatment can be made even without a three-group intervention design. As outlined in a special issue of *Development and Psychopathology* (Cicchetti & Hinshaw, 2002), beyond the question of whether it works, intervention designs are uniquely equipped to address the question of how to test theories of developmental psychopathology. If we can target a family process with an intervention, demonstrate using the appropriate controls that the intervention (A) produces the desired effect on the family (B),

and show that this effect is associated directly with changes in the desired outcome (C), then we have a powerful instrument for concluding that B has a causal connection with C. This would allow us to begin to confirm or disconfirm the theory on which the intervention was based.

A beginning move in the direction of identifying family mechanisms in psychopathology using intervention designs has been made in studies of EE in families with members diagnosed with Schizophrenia or Bipolar Disorder, as mentioned (Miklowitz, 2004; Pilling et al., 2002; Wahlberg & Wynne, 2001). Compared with traditional individual treatments of the patient, psychoeducational interventions with family members produce lower relapse rates after the patient leaves the hospital. Still needed in these and other intervention studies are detailed analyses of the changes in family interaction produced by these interventions and an examination of whether this change accounts for the variations in the patient outcomes.

Measurement and Statistical Issues in Correlational and Intervention Designs

Most studies of links between family functioning and psychopathology use measures and statistical analytic techniques more appropriate to the study of individuals, and occasionally dyads, than to the assessment of the family as a system.

Measurement. The source of information about the family can come from one or more family members (mother, father, child) or outside observers (family friends or researchers). The focus of that information can be on individual family members, dyads, or the system as a whole. To complicate an already complex picture, the information can be obtained in different contexts: individual interviews, dyadic interactions, the family system as a whole, or the family in the community. That is, there are 4 sources (multi) 3 foci (multi) 4 contexts, or 48 potentially different perspectives on family functioning. Only a few of these can be included in any single study. What is most seriously lacking from current research, in our view, is the examination of the family as a whole using systemic concepts to assess how the family operates.

The most well-established family system measurement systems (see earlier discussion), the McMaster model and the Beavers model, use family interviews to obtain data; this severely limits the technique to children who can talk and focus throughout a long session. A promising example of a new approach to families with infants, described briefly earlier, is the Lausanne triogue play procedure (Fivaz-Depeursinge, 2003; Frascarolo, Favez, Carneiro, & Fivaz-Depeursinge, 2004), in which mothers and fathers

interact together with their infant and the coding of this interaction yields measures of both family structure and affective process.

Statistical Techniques Until recently, one of the chief impediments to family systems research has been statistical techniques directed toward a linear analysis of the effect of x on y , using either analysis of variance or multiple regression techniques. More recently, structural equation modeling, time series analyses, and hierarchical linear modeling allow researchers to contrast models in which there is a reciprocal effect of A on B and B on A . These techniques move us closer to testing hypotheses promulgated by family system theories 50 years ago.

What Is Needed?

In sum, despite the fact that there is considerable evidence that treatments based on family systems theories are effective, the evidence supporting family systems theories of psychopathology is at a preliminary stage. Families with a severely mentally ill member communicate differently from families without a diagnosed member, but it is not possible to tell whether the communication deviance is at the root of the disorder. The best evidence concerning the validity of family systems theories will come from follow-forward studies, with measurement that focuses on the system as a whole and demonstrates that the family-level measures contribute uniquely to our understanding variations in psychopathology and adjustment, over and above the contribution of risk factors in individual and dyadic domains. Because this kind of study is rare, and because so many studies will be needed to discover the links between measures of family-level functioning and each specific disorder we hope to understand, opportunities for research in this area will keep many investigators very busy for many decades.

Family Risk Factors and Psychopathology

In our view, the bulk of the evidence used to support the validity of family systems theories comes from family risk factor studies of the variables that each theory emphasizes as central to that approach. That is, family system theories may be located in cell 9 of our matrix (Figure 14.2), but different family theories have different emphases on specific risks, and these risks can be located in each of the remaining cells or in the interactions among them. We describe a number of examples of empirical evidence that provides support for the hypothesis that family risk factors

play an important role in the understanding of psychopathology in clinical populations.

Genetic-Family System Interactions

There is no doubt that severe psychological disorders (Schizophrenia, Bipolar Disorder, Major Depression, Anti-social Personality Disorder, and others) run in families (Gottesman et al., 1972; Meehl, 1962; Rosenthal, 1967). Given a diagnosed patient as an index, relatives are more likely to be diagnosed with that disorder than a nonindex control of the same age, sex, and general life circumstances. The central task in the field of behavioral genetics has been to disentangle the confounding due to the fact that closely related family members tend to live together, making it difficult to assess genetic effects separately from environmental effects. Earlier, we described studies of heritability that compare monozygotic twins (MZ, identical), dizygotic twins (DZ, fraternal), families with two or more nontwin children, and sometimes families with adopted at-risk children. In combination, these studies represent attempts to tease apart the contributions of genetic and family environmental risks to psychological disorders.

A related, more central question for the field of developmental psychopathology is why some individuals with family genetic vulnerabilities develop disorders and others do not. The most general answer to both of these questions originated more than 4 decades ago in a diathesis-stress model, which conceptualized genetic factors as a diathesis (vulnerability) that results in a disorder if triggered by sufficiently high levels of specific environmental stressors (Tienari, 1991; Wahlberg et al., 2004). The early work tended to describe environmental stressors in vague terms as effects not accounted for in estimates of heredity. Recent behavioral genetic studies create a more differentiated picture of the way careful consideration of genetic factors in research designs provide powerful support for the hypothesis that family risk factors play a causal role in the development of psychopathology.

Heritability-Environment Interaction.² A very sophisticated Finnish Adoptive Family Study provides preliminary evidence for interaction of heredity and family environment. Tienari and his colleagues (Tienari, 1991; Wahlberg et al., 2004) identified 155 people with at least one parent diagnosed with Schizophrenia, who were adopted away, and 186 control cases, also adopted away,

²The discussion in this section has benefited from a presentation made by Avshalom Caspi to an NICHD-sponsored group considering Family Change and Variation (Los Angeles, February 2005).

whose parents had no psychotic disorder. Using Singer and Wynne's (1965a) procedure for assessing communication deviance among the adoptive parents, in combination with other diagnostic material, these researchers produced a global rating of each adoptive family's level of functioning. Early reports show that 34% of the children whose *biological* parents were not psychotic, but 62% of the children with a psychotic biological parent, were diagnosed with schizophrenic spectrum disorders when their adoptive parents were rated as disturbed in terms of psychopathology or communication deviance. By contrast, when the adoptive parents were rated as mentally healthy, 4% of the children with nonpsychotic biological parents and 3% of the children with psychotic biological parents were diagnosed with schizophrenic spectrum disorders. Given this research design that separated biological risks associated with heredity and family risks associated with the adoptive living environment, this study provides strong evidence that genetic vulnerability brought by the adoptee is more likely to result in psychopathology in the context of mental illness or disordered communication in the adoptive family environment. Conversely, adoptive parents who function well may be able to protect children from the risks associated with having a biological parent with Schizophrenia. The later results will be especially important, as the youngest adopted children have not yet reached the primary age for risk for Schizophrenia.

An important point has recently become central in behavioral genetics research: Heritability estimates hold *only for a specific population*. In a paper that helped to reframe the discussion of this topic, Turkheimer and his colleagues (Turkheimer, Haley, Waldron, D'Onofrio, & Gottesman, 2003) showed that the heritability index of IQ is almost zero at low levels of socioeconomic status, but very high in financially well-off samples, where it explains about 60% of the variance. Parental treatment that fosters similarity between siblings (shared family environment) or difference between siblings (nonshared family environment) explains little of the variation in IQ in high-income families but about 60% of the variation in low-income families. How heritable is IQ? How important is family interaction in explaining variance in IQ? The answers depend on the socio-cultural context of the families we study.

Using Genetic Controls to Study Environmental Variation. We noted that twin studies are now being used in a new way: to control for genetic influences so that the effects of family environmental variation become clear. In the Environmental Risk Longitudinal Twin Study, Caspi and Moffitt and their colleagues (Caspi et al., 2004) stud-

ied a nationally representative sample of British families with MZ and DZ twins. Mothers were asked to describe each twin for 5 minutes, as in the studies of expressed emotion described earlier. Using ratings of negativity and warmth expressed toward each 6-year-old twin in mothers' speech samples, the investigators found that within each pair (controlling for genetic factors), the twin whose mother expressed more negativity and less warmth toward him or her was rated by the classroom teacher as showing more antisocial behavior at school.

Biological Relatedness and Family Structure. Twin studies are not the only way of studying the impact of biological and social relatedness in families. Hetherington and her colleagues (1994) examined data from the national sample from the Nonshared Environment in Adolescent Development Project (Caspi et al., 2004). Eliminating the MZ and DZ twins from a sample of families with at least two same-sex adolescent children, the researchers studied non-stepfamilies, simple stepfamilies in which all siblings were the mother's biological children and the father's stepchildren, and complex stepfamilies in which the children were combinations of his, hers, and theirs. The last two groups allowed the investigators to contrast family systems in which the children had different degrees of biological relatedness to each other and to their parents. The investigators found few differences between nonstepfamilies and simple stepfamilies in the adjustment of the children or the quality of marital and parent-child relationships. In complex stepfamilies, however, more problems were observed in the family relationships, and the adolescents showed less social responsibility and higher levels of externalizing problems. In the stepfamilies, greater caretaking and warmth was found when parents were interacting with their biological children rather than with their stepchildren. That is, genes also have an impact on the social construction of relatedness and may influence attitudes and behavior of children, parents, and others outside the nuclear family. Judgments about the importance of genetic relatedness become very important in discussions of stepfamilies, adoption, and gay and lesbian families.

Measuring Gene-Environment Interactions. In studies of heritability, the impact of genetic factors on psychopathology is inferred from the differences in correlations between MZ and DZ twins. Recent methods of measuring gene functions and dysfunctions directly, rather than estimating them from family heritability, are providing more precise indicators of genetic risk. In a nationally representative sample of more than 1,000 children in Dunedin,

New Zealand, Caspi and Moffitt and their colleagues (Caspi et al., 2002) measured the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA), located on the X (male) chromosome. Deficiencies in this gene affect neurotransmitters such as norepinephrine, serotonin, and dopamine, which have been linked with male antisocial behavior (Huang et al., 2004). Also linked with antisocial aggressive behavior is childhood maltreatment by parents (Cicchetti et al., 2000; Dodge, Pettit, & Bates, 1997). The Caspi et al. study found that when the children's MAOA activity was low (indicating deficiency), there was a very high incidence of diagnosed Conduct Disorder in adolescence and elevated levels of disposition toward violence, convictions for violent offenses, and Antisocial Personality Disorder in adulthood. Conversely, high MAOA seemed to protect children who had experienced early maltreatment from developing antisocial behaviors later on. Note that both longitudinal studies by Caspi and Moffitt are of nonclinical populations. Nevertheless, these populations included individuals with a formal *DSM-IV* diagnosis. Behavior geneticists argue that limiting studies to clinical populations reduces the sample variance in ways that can lead to biased estimates of both genetic and environmental effects on psychopathology.

Among many important implications of this research and of other studies cited in this section are two conclusions about the family as a system. First, genetic heritability is affected by the social context in which it operates and is measured. Second, genetic heritability affects the social environment through its impact on the behavior of family members by influencing their behavior in ways that have environmental impact. Although research studies have demonstrated impressively that these interactive effects occur, we do not yet have a clear idea of the mechanisms by which genetic factors affect environments and how family and other environmental factors "get under the skin" (Taylor, Repetti, & Seeman, 1997) to affect biological processes. Third, because behavior genetics analyses have been applied to a limited number of disorders in a limited number of social contexts, it is not clear how the weighting of genetic, family, and other environmental influences holds across diagnostic categories and across cultures.

Couple Relationships and Psychopathology

Both symptomatic and clinically diagnostic levels of depression co-occur with marital dissatisfaction, conflict, and distress (e.g., Whisman, Uebelacker, & Weinstock, 2004). Unhappily married couples are more likely to be depressed, and depressed individuals are more likely to exist

in unhappy marriages. Although each domain influences the other, declines in marital satisfaction may play an etiological role in depression more often than vice versa (Whisman & Bruce, 1999). Some corroborating evidence comes from a review of therapy studies reporting that marital therapy is an effective treatment for depression when compared with no-treatment controls and, more important, is more effective than individual therapy with the depressed client (Teichman, 1997); the converse approach of treating depression in couples with marital problems has not been systematically evaluated. A more differentiated view of the marital quality link with depression comes from a short-term longitudinal study (Fincham, Beach, Harold, & Osborne, 1997), which suggests that for men, the causal path may lead from depression to marital dissatisfaction, whereas for women, the causal path may lead from marital dissatisfaction to depression. This is only one of many illustrations of the principle that gender affects the pathways between family risks and maladaptive outcomes.

We have noted throughout the chapter that couple relationship conflict and dissatisfaction are correlated with children's externalizing behavior in both nonclinical and clinical samples. Marital conflict is also associated with children's internalizing behavior, specifically anxiety and depression. In the Environmental Risk Longitudinal Twin Study, Jaffee and colleagues (Jaffee, Moffitt, Caspi, Taylor, & Arseneault, 2002) reported that, after controlling for genetic and nonshared parenting effects (behaviors toward siblings that enhance differences), domestic violence between parents was associated with significantly higher externalizing *and* internalizing behavior in children. Furthermore, the quality of relationships in the family had a particularly strong contribution to predicting comorbidity—children who were both aggressive and depressed. Note that in behavior genetics studies, the distinction between genetic and environmental effects is not entirely clear. In this case, genetic factors may contribute to both the parents' tendency to engage in violent behavior and to the child's vulnerability.

Parenting and Psychopathology

As examples of how parents can contribute to the onset or maintenance of children's problems, we discuss parental maltreatment, and children diagnosed with Attention-Deficit/Hyperactivity Disorders and disorders of attachment.

Parenting Behavior. Maltreatment is a serious social problem, with American rates of reported child abuse in 2002 ranging from 16 per 1,000 0- to 3-year-olds to 6 per

1,000 16- to 17-year-olds. This results in more than 2 million children who are abused in a given year, and an estimated 1,400 fatalities resulting from abuse of children by their parents and other adults in the household. It is clear that although maltreatment is manifest in the parent-child relationship, the etiological picture involves a system of by now familiar family risk factors. Building on Belsky's (1980) ecological model, Cicchetti and his colleagues argue that maltreatment involves (1) maladaptive biological and psychological resources in maltreating parents, especially depression, and drug or alcohol use; (2) unsupportive and aggressive marital relationships; (3) parent-child relationships in which the parents are more controlling, hostile, and coercive make more negative attributions about their children's behavior, and are less affectionate than nonabusing parents; (4) a history of abuse across generations (though the evidence is largely retrospective); and (5) stressors in the society outside the nuclear family, including racism, poverty, dangerous neighborhoods, unemployment, and lack of supportive social networks (for integrative summaries, see Cicchetti, 2004; Cicchetti & Lynch, 1995; Cicchetti & Toth, 2003).

A less severe but no less important form of negative interaction can be seen in the Patterson group's concept of coercive parent-child relationships. Structural equation models consistently reveal links between coercive parent-child patterns and children's and adolescents' aggression both inside and outside the family (Dishion & Patterson, 1997; G. R. Patterson, Reid, & Dishion, 1998). The model has also been tested in intervention studies demonstrating that reductions in coercive parenting are followed by decreases in adolescent aggression. Whereas coercion represents an active, intrusive parenting style, Reid, Patterson, and Snyder (2002) summarize 3 decades of research showing that parental disengagement, especially in the form of lack of monitoring of adolescents, also represents a significant risk factor for adolescent aggression. This variable is usually assessed by phoning parents in the evening and asking them if they know where their children are. We focus here on parenting, but, as in Cicchetti's ecological model of maltreatment, Capaldi and colleagues (Capaldi, Pears, Patterson, & Owen, 2003; Pears & Capaldi, 2001) present a multidomain family risk model in which parent-child relationships play a necessary but not sufficient role in explaining children's and adolescents' maladaptive behavior.

All of these studies attempting to link parenting behavior with child and adolescent outcomes are subject to the same caveats about inferring causality that we have discussed throughout the chapter. Harsh physical punishment or legally defined abuse is clearly detrimental to children and cannot

be justified, but it is not always possible to determine whether child temperament or other characteristics play some role in eliciting the parental behavior. Coercion is by definition a reciprocal construct, describing the escalating pattern created in the interaction between parent and child. Even monitoring, which clearly sounds like a parental behavior, can be an ambiguous construct; investigators point out that some adolescents spontaneously tell their parents where they are going and where they are, so that the correlations between monitoring and low aggression may reflect the quality of the relationship, not whether parents take an active, coercive part in forcing their children to reveal information concerning their whereabouts.

Parenting and Children's Attention-Deficit/Hyperactivity Disorder.³ A case for a bidirectional view of parenting behavior and children's characteristics can be seen very clearly in studies of children diagnosed with ADHD. There is no doubt that there are strong heritability factors in the etiology of both attention deficits and hyperactivity, but there is also evidence that the stress experienced by parents of children with these symptoms increases the probability of negative family interactions (C. Johnston & Mash, 2001). The lack of control, hyperactivity, and defiant behavior shown by these children elicit harsh or permissive reactions in parents; these parenting behaviors predict antisocial and noncompliant behavior assessed later on, even after controlling for the child's earlier ADHD behavior (Anderson, Hinshaw, & Simmel, 1994). Comparing families with a male child with and without a diagnosis of ADHD, Hinshaw and his colleagues (Hinshaw, Zupan, Simmel, Nigg, & Melnick, 1997) found that in the ADHD sample only, mothers' authoritative parenting beliefs predicted social acceptance by the boys' peers in a summer camp, even when their behavior with those peers was observed to be quite negative. To the extent that parenting beliefs were reflected in behavior, the results are consistent with the hypothesis that an authoritative parenting style can protect children with ADHD from peer rejection, but that there may be many other routes to peer acceptance for boys without ADHD.

Finally, in a variation on the genetic designs described earlier, twins with low birthweight were the focus, because low birthweight is a risk factor for ADHD (Tully, Arseneault, Caspi, Moffitt, & Morgan, 2004). Only for these initially small twins did mothers' warmth in a 5-minute

³The discussion in this section has benefited from discussion with Stephen Hinshaw.

speech sample protect children against symptoms of ADHD 6 years later. All of these findings illustrate the general principle that parenting behavior interacts with child characteristics to predict adaptive or maladaptive outcomes.

Attachment Relationships. Our emphasis here shifts from a focus on parents' behavior to the inclusion of children's inner working models and behavior in situations in which they experience a separation or threat of loss of the parent. Four ways of coping with this loss have been identified in laboratory studies of attachment (Ainsworth & Wittig, 1969; Lyons-Ruth, Alpern, & Repacholi, 1993). When a parent comes back into the lab room, his or her 12- to 18-month-old may (1) fuss but seek the parent as a secure base before continuing play (secure); (2) anxiously avoid the parent; (3) angrily attack the parent; or (4) become disorganized. Insecure attachment in the parent-child relationship has been associated with an expectable range of family risk factors, including parents' psychopathology, adolescent hospitalization (J. P. Allen, Hauser, & Borman-Spurrell, 1996), parents' insecure working models of attachment with their parents (the grandparents; Fonagy, Steele, & Steele, 1991; van Ijzendoorn & Bakermans-Kranenburg, 1997), and marital distress (Owen & Cox, 1997).

The overall classification of securely attached versus insecurely attached is relatively stable over long periods of time in *middle-class but not economically disadvantaged samples* (Vaughn, Egeland, Sroufe, & Waters, 1979). In low-income samples, changes in the child's attachment status have been related to changes in the circumstances of the parents, especially in the case of establishing or ending a romantic relationship with a partner (Egeland & Sroufe, 1981; Vondra, Hommerding, & Shaw, 1999). Infants with an early history of secure attachment are likely to show a number of positive adaptive traits in childhood and adolescence, including less anxiety and more empathy and social competence (Egeland & Carlson, 2004). By contrast, early insecure attachments represent risk factors for anxiety, depression, and low social competence.

Several investigators who take a longitudinal perspective on the links between early attachment and later psychopathology have suggested that insecure attachment is not simply an index of psychopathology or a direct cause of psychopathology (J. P. Allen et al., 1996; Cicchetti & Barnett, 1991; Davies, Cummings, & Winter, 2004; Sroufe, Carlson, Levy, & Egeland, 2003). Rather, patterns of earlier insecure attachment, in combination with difficulties in family relationships, set in motion forces that move the child in the direction of psychopathology over time if they are not counteracted by buffers in the family or other as-

pects of the child's environment (Egeland & Carlson, 2004). For example, maltreated children with perceptions of high positive relatedness to their mother were more depressed than nonmaltreated children, but less depressed than maltreated children who did not describe positive relatedness with their mother (Toth & Cicchetti, 1996).

Intergenerational Transmission. We have already noted that most studies of transmission, including those that employ the Adult Attachment Interview (George, Kaplan, & Main, 1985), rely on retrospective data. There are some new findings from longitudinal studies of clinical populations that use observations of parents in generation 1 (G1) as they interact with their children (G2), and then observations of G2 as adults parenting their own children. In a useful review, Serbin and Karp (2004) point out that consistency across generations is higher when the assessments of parents and children in G1-G2 occur at approximately the same age as the assessments of parents in G2 and G3 (Capaldi et al., 2003).

The fact that children tend to resemble their parents and to think (B. A. Miller, 2005) and behave (Bengtson, 1996; Luescher & Pillemer, 1998) in similar ways does not tell us a great deal about what has been transmitted or how the transmission has occurred. Five theoretical explanations of intergenerational continuity dominate the current scene. First, as we have just seen, attachment theory assumes that adults have developed working models of parent-child relationships based on experiences with key attachment figures in their family of origin, and these working models shape their expectations and reactions during interactions with their children (Bowlby, 1988). Second, some of the repetition of relationship patterns across generations is affected by genetic and other biological mechanisms (Plomin, 1994). Third, psychoanalytic formulations focus on the child's identification with the same-sex parent and the internalization of that parent's superego, both of which provide guidelines for what constitutes appropriate behavior in family relationships (Fraiberg, 1975; S. Freud, 1938). Fourth, in turn, these interactions between parent and child result in the child's creation of working models that lead to the repetition of secure or insecure attachment patterns in the next generation. Fifth, social learning theorists (Bandura, 1977; G. R. Patterson, 1975) offer a simpler explanation that does not rely on assumptions about the child's inner world: In the process of observing adults interact with others and noting which behaviors are reinforced or punished, children learn patterns of family behavior that they tend to repeat when they form their own family.

Most studies of intergenerational transmission focus on the parent-child relationship. Both family systems models and family risk models suggest that attention should be paid to three additional perspectives on continuities and discontinuities of family patterns. First, as we (P. A. Cowan, Bradburn, & Cowan, 2005) and Caspi and Elder (1988) have shown in studies of nonclinical families, children with behavior problems who are involved in conflictful relationships with their parents, and may be insecurely attached to them, are more likely to form conflictful marriages, which are followed by combative parent-child relationships, which predict problematic behavior in their children. Second, new work on family rituals provides a more system-focused perspective, suggesting that in daily rituals such as gathering together for family dinners and anniversary or religious rituals, family members in well-functioning families coconstruct stories that create family myths and preserve family values, whereas the absence of such rituals is often seen in families experiencing various forms of distress (Fiese, 1992; Pratt & Fiese, 2004). Finally, due to both genetic and environmental factors, families tend to remain in the same social class from one generation to the next, and the repetition of stressors may also contribute to continuity of adaptation across generations.

Families and Peer Groups

By referring more generally to measures of externalizing and internalizing in discussing family factors in psychopathology, and not focusing on the fact that these measures often refer to behavior with peers in schools and other social settings, we have not conveyed the central importance of the linkage between family and peer relationships. In an analysis of the data from the Oregon Social Learning Study, G. R. Patterson, Dishion, and Bank's (1984) longitudinal study of aggressive boys showed that coercive parent discipline interacted reciprocally with irritable exchanges between the target child and other family members. Furthermore, irritable exchanges within the family, especially between siblings, were described as providing "fight training" that generalized to the peer group in seventh grade and 10th grade and was associated with peer rejection, one of the major risk factors for adolescent antisocial behavior.

The question of whether fighting leads to peer rejection or rejection leads to fighting has been debated for a long time (see Parker & Asher, 1987, for the beginning of this debate). Evidence supporting the hypothesis that peer rejection may come first was found in our own longitudinal study (P. A. Cowan & Cowan, 2004). Teacher-reported peer rejection in first grade predicted antisocial behavior

in fourth grade (stealing, fighting, lying), over and above earlier aggressive behavior in kindergarten. Negative interactions between the parents and between parents and children in prekindergarten and kindergarten were risk factors for peer rejection in first grade. Furthermore, based on data from the intervention with the parents as couples, we were able to show that intervention-induced positive changes in marital and parenting relationships resulted in the children's suffering less peer rejection in first grade.

Multiple Risk Models

In each of the previous sections, we saw how researchers were stretching to go beyond two domains or levels of analysis at a time and include yet another risk domain in their attempts to predict and understand psychopathology. In this section are a few studies that attempt to bring all of the domains together.

Correlational Studies. At Bradley Hospital and Brown University School of Medicine in Rhode Island, a group of researchers (Dickstein et al., 1998) is attempting to validate family systemic approaches to psychopathology by constructing measurement models that rely on multiple methods and perspectives on three levels of family interaction: marital, parent-child, and whole family. These models combine a risk factor and family systemic analysis of the family. In about 75% of their sample of 185 families, mothers had a lifetime history of mental illness. The investigators' measurement scheme followed the McMaster model of normal family functioning described earlier, which included the McMaster Structured Interview of Family Functioning, a dinnertime observation, and individual questionnaires to arrive at a family-level assessment, along with questionnaires that describe the quality of marital and parent-child relationships. Although almost all the measures were significantly intercorrelated, each also showed some independent contribution to explaining family health and maladaptation.

A unique feature of this study is that the researchers examined the correlations between family variables and groups representing a number of diagnostic categories: Major Depression, Anxiety Disorder, Bipolar Disorder, and a miscellaneous group, comparing them with no-illness controls. As expected, family-level variables, marital variables, and parent-child variables (both father-child and mother-child) all revealed some significant differences between the no-illness controls and the clinical groups, with little differentiation among diagnostic groups except for the fact that depressed mothers were the only ones to show significantly lower quality of parent-child relationships.

Consistent with the family systems assumption that the whole is not equal to the sum of the parts was the finding that the presence or absence of psychopathology in the mothers was much more strongly related to measures of whole-family functioning than to measures of marital or parent-child relationships. In other words, the functioning of the family as a whole was more disrupted than the dyadic relationships.

Multidomain Interventions In response to the difficulty of treating families with adolescents who abuse drugs, several researcher-clinicians have demonstrated the importance of considering levels of psychopathology in each family member, patterns of interactions during conjoint family treatment, and multiple settings in which families are embedded (high-crime neighborhoods, ineffective schools, drug-encouraging peer groups, inaccessible health care systems, and inconsistent juvenile justice systems). The task of the therapist is not to intervene in all of these systems, though some attempt to work with schools and peer groups, but to help the adolescent and family mobilize resources and avoid contexts that reinforce drug-abusing behavior (Liddle, 1995; Liddle et al., 2001). Applications of this approach to the treatment of already identified families have been successfully extended to preventive interventions for high-risk adolescents who are not yet clinically diagnosed (Liddle & Hogue, 2000).

A conceptually similar approach to the treatment of delinquent adolescents and abusing families, multisystemic therapy was developed by Henggeler and his colleagues (Henggeler & Borduin, 1990; Henggeler, Schoenwald, & Pickrel, 1995). Both the Liddle and Henggeler multidomain treatments were developed in a context in which studies of traditional child psychotherapy showed significant effects in studies conducted in university settings, but not when conducted in community clinic settings (Weisz, Donenberg, Han, & Weiss, 1995). Henggeler and colleagues argue that multisystemic therapies not only rise to the challenge of the level of pathology of clients in community clinics, but also fit better with the ideology of community clinics, which are more likely to use a combination of strategies, including pharmacological treatment, parent training, and school interventions, to address the problems of their clientele.

Two large-scale intervention programs developed in the 1990s also attempt to match a multidomain treatment approach to their multilevel conceptions of psychopathology. The Multimodal Treatment Study of Children with Attention-Deficit/Hyperactivity Disorders used a randomized clinical trials design to compare four 14-month treatments

of boys with ADHD: (1) a double-blind drug trial; (2) a set of behavioral treatments that included group and individual parent training, an intensive summer camp treatment, and school-based interventions; (3) a combination of the first two; and (4) treatment as usual in the community. Different analyses produced different findings, but overall, the combined drug and behavioral treatments produced more positive outcomes than either the behavioral treatments alone or the treatment as usual conditions (Owens et al., 2003). Consistent with the systematic themes we have been discussing here, both parental depression and child severity of problem were associated with less successful outcomes. In addition, reductions in parental negative discipline were responsible for positive child outcomes in this condition and only in this condition; when families were assigned to the combined behavioral treatment and drug treatment, improvements in discipline were associated with improved social skills and reduced externalizing behavior into the normal range.

Finally, a multimodal prevention program attempted to intervene early with children identified as at risk for developing conduct problems because they were already highly aggressive in kindergarten. The program combined individual social skills training with parent training programs and classroom behavioral interventions. Follow-up assessments showed that there were significant advantages for the treatment groups compared with the no-treatment groups (Conduct Problems Prevention Research Group, 1999a) and significant effects of the classroom intervention (Conduct Problems Prevention Research Group, 1999b). The success of the interventions appeared to stem from positive changes in targeted risk factors (e.g., the child's hostile attribution bias and problem-solving skills, harsh physical parenting; Bierman et al., 2002).

Tentative Conclusions about Family Risk Factors and Psychopathology

Our summary of studies makes clear that there is some support for both the family systems and family risk models of psychopathology. Many studies provided evidence that two or more of the five domains of family life we described in Figure 14.1 accounted for unique variance in a number of pathological outcomes. Other studies also provided evidence in support of the nine-cell matrix, incorporating biological, psychological, and social risk factors in some combination and paying attention to both internal and external sources of adaptation and maladaptation.

Despite these examples of how family risk domains are associated with various clinical diagnoses, there are still

important gaps in our summary and in the literature itself. In this section, we have provided evidence of family factors in only a few diagnostic categories. Schizophrenia, depression, Bipolar Disorder, and aggression have been most frequently investigated, but there is some work on the more internalizing disorders—anxiety disorders, eating disorders, drug and alcohol abuse—and some on family factors in cognitive and academic competence.

An emerging concern in the literature on developmental psychopathology is that disorders are often comorbid (e.g., Davison & Neale, 1996), but we were able to find only one family study (Jaffee, Moffitt, Caspi, Taylor, & Arseneault, 2002) that investigated the links between family factors and comorbidity. Finally, although there has been increasing attention paid to the idea of pathways and trajectories in the study of developmental psychopathology, it is still not clear how family system processes or risk factors steer children and adolescents toward specific diagnostic categories—why conflict and negative interactions in marital, parent-child, and three-generational relationships lead some children in the direction of externalizing disorders, some toward internalizing, some toward both, and some toward adequate or above-adequate levels of functioning.

DEVELOPMENTAL PSYCHOPATHOLOGY IN THE CONTEXT OF CHANGING FAMILIES

In this section, we shift theoretical frames for describing families from the process and structure conceptions of psychologists, psychiatrists, social workers, nurses, and other mental health professionals to “big picture” social trends studies from the fields of sociology and demography. The historical view of family change that follows here focuses on demographic characteristics such as age, income, and ethnicity and family structure in the sense of legal definitions and living arrangements such as cohabiting, married, separated, and divorced. We present two conflicting interpretations of the meaning of the changes, one suggesting family decline over time and the other family resilience. We discuss this as a background for considering whether family system and family risk factor theories of developmental psychopathology require modification in light of the realities of family life in the twenty-first century.

Definitions

One key issue in contemporary discussions of family life is how inclusive or restrictive the definition of family should be. Current inclusive definitions center around the idea that

a family is a constellation of two or more people “related by birth, adoption, marriage, or choice . . . with socioemotional ties and enduring responsibilities, particularly in terms of one or more members’ dependence on others for support and nurturance” (K. R. Allen, Fine, & Demo, 2000, p. 2). This definition encompasses couples without children, single parents with a child, and social units formed by choice, including adults who are “fictive kin,” members of a two-generational commune, and gay and lesbian parents and their children. At this time in U.S. history, there are researchers and political activists who oppose the inclusion of some alternative family forms in the definition of family, particularly gay and lesbian relationships. The controversy has become part of contemporary political debates in which some argue for a definition that encompasses diverse family forms and others advocate constitutional amendments or laws that would have the effect of limiting the rights and privileges associated with family to married heterosexual parents with children. The debate is not new. Twenty-five years ago, President Carter’s 1980 White House Conference on the Family ended prematurely when factional squabbles emerged about the same issues (S. L. Zimmerman, 2001, pp. 21–22).

Political disagreement about the definition of family is directly relevant to the study of developmental psychopathology. If nontraditional family arrangements are considered risk factors for children’s development and adaptation, then family structure becomes an indicator of potential psychopathology. One obvious strategy to resolve the issue of defining risk factors is an examination of empirical studies on the topic, but as we show later in this section, there are profound disagreements about the interpretation of existing research results, and some data do not address these dilemmas directly.

A Century of Change in Family Life

One of the most startling demographic shifts in family life in the past century is the fact that people live longer than they used to. Men and women born in 1900 could expect to live approximately 48 years and 50 years, respectively.⁴ By contrast, men and women born in the year 2000 could ex-

⁴Most of the trends described in this section are based on data from U.S. Census reports. We cite specific authors who have contributed specific analyses. Despite the fact that the data are drawn from the U.S. Census, we found variations in different reports of the same trends, based on the year of publication and on the base data used by different authors in calculating percentages. The figures here represent our best estimates from various sources, based on the information available in 2004.

pect to live to the age of 74 and 80, respectively. Also, family size has been reduced dramatically. The average of four children per family in 1900 has been more than cut in half by 2000. A number of notable changes in marriage have taken place in the past 50 years. The mean age of marriage has been rising (from 23 to 27 years for men and from 21 to 25 years for women). The proportion of adults never married rose from 6% of all women age 30 to 34 in 1960 to 19% in 2000, and from 9% to 30% of men, with especially high rates of nonmarriage in African American communities. Of course, the most frequently cited statistic about marriage is the rising incidence of divorce, which doubled from 1900 to 1960 and doubled again by 1980, although it seems to have leveled off or even declined in the last 2 decades of the twentieth century.

Not only are children more likely to live without two parents in the home at night, but in a majority of married and cohabiting two-parent families, both parents are involved in paid work outside the home during the day. For many children, this means less adult supervision than in prior years. Changes in attitudes concerning the role of women, and economic circumstances in which real family income declined, also propelled this shift from 1950, when 12% of women worked outside the home, to the beginning of the twenty-first century, when 67% of married and single mothers of children under 5 worked outside the home at least part time.

In 1900, only 10% of teens spent some time in high school; 100 years later, only 10% fail either to complete high school or receive their GED equivalent (Sealand, 2003). The marked lengthening of school careers, the impact of child labor laws that prevent children under the age of 18 from working full time, and an emerging tendency for offspring in their 20s to live with their parents after they finish college combine to extend adolescence and delay young men's and women's transition to adulthood (Settersten, Furstenberg, & Rumbaut, 2005).

These demographic shifts are related directly to the fact that families in the United States are more diverse than they used to be (Demo, Allen, & Fine, 2000). Clearly, children and adolescents now live in a variety of family arrangements. If we focus on families with two biological parents, there are children living with parents who are married or cohabiting, others living with one parent following separation or divorce, and others still who live with one parent who is a member of a couple who never married or lived together. Some of the never-married, noncohabiting couples are in romantic relationships that could reasonably have some impact on the children; some children living with their mother have never met their father. In addition to

families with two biological parents, there are stepparent families, adoptive families, and foster families. All of these categories of family structure have existed before, but over the past century the proportion of families with two married biological parents and children has contracted to approximately 25% of all families, and membership in the other categories has increased markedly.

Other demographic changes buttress our claim that the United States is increasingly a land of family diversity. In 1900, the non-White population of the country was 10% to 12% overall, and about 13% for children (Hernandez, 1996). By 1980, slightly more than 26% of Americans were children of color (8.9% Hispanic, 14.9% African American, and 2.2% other). By 1990 the figures increased again, to 12.3% Hispanic and 15.4% African American, and by 2030, it is estimated that a child of color will no longer be described as minority. Differential birth rates, foreign adoption, and immigration have all contributed to this increasingly diverse portrait of American family members.

Should We Equate Family Change with Family Decline?

Two starkly contrasting views of family change have emerged, one, an extensive body of writing characterizing the changes as evidence for "family decline" and another, more limited body of work, evaluating the same changes as evidence for "family resilience."

The Family Decline Interpretation

In the 1990s, a number of sociologists and demographers (Popenoe, 1993; Waite & Gallagher, 2000), leaders of conservative family organizations (Dobson & Bauer, 1990), and politicians (Bennet, 1992), became alarmed by the changes in family life that we have described, interpreting them as leading to the decline of the American family and, by implication, the decline of families in most Western industrialized societies. From the roughly simultaneous shifts in family size, marriage rates, divorce rates, single parenthood, and mothers of young children working outside the home, these interpreters of family trends draw conclusions about the source of increases in the incidence of marital problems and divorce and of behavior problems in children and youth. Couples and their children are not doing well, they argue, *because* of the shifts away from traditional nuclear family structures. They attribute the shifts to a motivated move away from "family values" toward adults' self-focused concern with their own development:

“Quite clearly, in this age of the me-generation, the individual rather than the family increasingly comes first” (Popenoe, 1993, p. 538).

The Family Resilience Interpretation

Another interpretation of the same historical data has sometimes been characterized as demonstrating family resilience (Amato, 2005; Demo et al., 2000; Skolnick, 1991; Stacey, 1996). The resilience interpretation holds that, although it is true that many social indicators are indicative of change in the family, the changes by and large represent flexible adaptations to changing and challenging circumstances. Men and women are wise to marry later because marriages of younger couples are more at risk. It is sensible for couples to be wary of making commitments, given what they see happening to the marriages of their parents and friends. Some argue further that given a more complex, difficult, and diverse social structure, it is something to be celebrated that so many families do relatively well.

The family resilience view argues that the negative consequences of family change have been overstated. Single parenthood does not represent the arrangement that most men and women aspire to, according to interviews with children, adolescents, and adults (Ahrons, 2004; McLanahan, 2002), but most single mothers manage to raise children who function successfully in their world. Worries about mothers working outside the home are greatly exaggerated. In general, outside of children of mothers who are employed during the child’s 1st year (Baydar & Brooks-Gunn, 1991), few differences have been found between children of mothers at home and those employed outside the home (Harvey, 1999). Some of the differences that have been found are due to selection factors (Vandell & Ramanan, 1992), especially economic or marital circumstances that propel some reluctant mothers into the workforce. It has been suggested that mothers who work outside the home bring not only economic benefits, but also positive role models and examples of making successful, productive contributions in life, especially to their daughters (e.g., Moorehouse, 1993). Another argument supporting the family resilience view is that even though divorce can be difficult for all family participants, it may shield the child from ongoing conflict or violence between the parents, and many children of divorce lead successful lives over the long haul (Ahrons, 2004; Amato, 2000).

Problems with the Family Decline Interpretation

Although the fact that the demographic trends in many social indicators follow a similar time line makes the family

decline interpretations seem plausible, we believe that this interpretation of the data is fundamentally flawed in a number of ways.

Traditional Families as the Gold Standard. Most interpretations of family decline hold up traditional families—two-married-parent families with fathers at work and mothers and children at home—as the standard of comparison against which historical changes in family life are to be evaluated. As we briefly described earlier, many traditional two-parent families are under considerable stress; significant proportions of parents show significant depressive symptoms and/or marital strain, and children show diagnosable problems early in their school careers. The data on family arrangements and relationship satisfaction suggest that even if risks of difficulty are higher in nontraditional families, a return to traditional arrangements would provide no guarantee that adults and children would fare much better or that family relationship quality would improve.

Most of our references to traditional families focused on heterosexual parents. There is a growing body of research focused on families with same-sex parents, primarily lesbian families. Contrary to the implicit or explicit expectations of family decline theorists that these families are less stable and less supportive of children’s adaptation, the evidence suggests that children of lesbian and gay parents are not significantly different from children of heterosexual parents on a number of major indicators of adjustment and adaptation (Arendell, 1997a; Golombok & Tasker, 1994; Lamb, 1999; C. J. Patterson, 2002). Stacey and Biblarz’s (2001) survey of the literature argues that findings revealing that children of lesbian and gay parents show superior adaptation have been downplayed or overlooked in these studies.

Problems of Causal Inference. There are two major difficulties in inferring that associations between family change and increases in psychopathology are causally connected. First, a common practice in the evaluation of social trends is to note that two social indicators are changing around the same period of time and to conclude that change in one *causes* change in the other. To draw such a conclusion, it would be necessary to show that these changes co-occur within the same families. That is, assuming that there is an increase in youth violence over time, researchers would have to show that this increase occurred in “nontraditional” families or families that became nontraditional in the process of separation and divorce. Even then, correlation would not establish conclusive proof of causation.

Studies of families in transition have not produced results that unequivocally support the family decline argument. For example, as we have seen, although divorce and single parenthood represent risk factors for elevated levels of behavior problems in children and adolescents, there are more exceptions to the rule than exemplars of the decline hypothesis (Hetherington & Kelly, 2002); in fact, most children of single parents fare reasonably well. By reporting only the fact that there are statistically significant differences between family types, family decline authors overstate the magnitude of the effects to make it appear that changes in the direction of nontraditional family structures account for the major proportion of social problems and psychopathology in children and youth.

Conflicting Evidence for the Conclusion of Declining Well-Being of Children and Youth. A central implication from most of the social trends we described is that children and youth are living in less stable, less traditional families than they used to, and that, as a consequence, they are experiencing more difficulties than their age-mates in earlier times. The facts relevant to conclusions about trends for children and youth are quite difficult to come by because many of the social indicators of health, behavior, and well-being have been gathered systematically only since the 1980s. After an extensive search of the literature, we conclude that there is a very mixed picture concerning the claim that today's youth are in a state of intellectual, emotional, and moral decline.

We know that children's physical health and life expectancy have improved dramatically from 1900 to 2000. In addition, from 1939 to 1970, both African Americans and European Americans showed a marked reduction in the proportion living in poverty, with a leveling off in the subsequent 30 years (Brown et al., 1999). Public concerns about the state of American children and youth tend to focus on adolescent sexual behavior and teen pregnancy, substance abuse, and violence. There is no question that U.S. youth are more sexually active, and active at a younger age, than they were 100 years ago (Brown et al., 1999). Nevertheless, sexual risk taking defined as engaging in unprotected sex has declined since 1982. Although the proportion of unmarried teenagers having babies increased from the 1970s to the 1980s, the most recent data show that teen pregnancy has been declining since then. The declines are even more evident in some subgroups than others. For example, the overall rate of teen pregnancy dropped by approximately 20% in the 1990s, but by as much as 30% in African American teens (Ventura, Anderson, Martin, & Smith, 1998), and there are wide variations among states

in both the teen pregnancy rates and the declines in live births. The often-cited fact that teen pregnancy rates in the United States are much higher than those in other countries is mitigated somewhat by the observation that the differences are substantially reduced when race and income are statistically controlled (Kirby, 1999). In contrast with public perceptions of increasing problems (Guzman, Lippman, Moore, & O'Hare, 2003), teen violence and substance abuse also show declining trends.

What has risen considerably in the past 3 decades is the frequency of diagnosed mental illnesses in children and youth (Eberstadt, 2004). Mental health professionals are diagnosing an increasing number of children at younger ages with serious mental disorders, and many of those children are being treated with psychiatric drugs developed for adults. Diagnostic categories that have shown significant increases are ADHD (more males than females), eating disorders, and Asperger's syndrome and other autistic spectrum disorders. It is not clear whether the increases in incidence and prevalence of the disorders represent a true increase in the occurrence of psychopathology or whether the trends reflect increased attention to the mental health and illness of children and youth, increases in diagnostic skill, more efficient reporting and data collection, or media attention to these illnesses.

We are not arguing that the increases in child and youth mental illness are illusory, but rather that changes in the adaptation of young people require further systematic research before we can claim to understand the data. Whatever conclusion is ultimately drawn about historical trends, the picture is not consistent with the simple statement that the "decline" of U.S. families has been responsible for a crisis in U.S. youth.

No Proof That "Family Values" Play a Central Role in Family Change. A central feature of the family decline interpretation has been the conclusion that changing family values are the motivating force behind changing family trends, and the subsequent argument that a shift in family values would have a salutary effect. Although there are studies indicating that, on the average, there have been shifts in some aspects of family values over the past few decades (S. L. Zimmerman, 2001), we are aware of no data relevant to the claim that men and women who have less traditional family arrangements value self more and family less, or that troubled children and youth are more likely to have parents who hold self-focused rather than family-oriented attitudes.

Those who accept the interpretation that family values are responsible for family change in the past century fail to

consider the possibility that external social systems rather than internally held values may play a central role in how families are arranged. Families are embedded in the social and political structure of a society (Bronfenbrenner, 1979). Social and economic policies, and the institutions that administer them or fail to do so, have a great deal to do with the quality of family life. For example, despite a new government emphasis on promoting marriage (see later discussion), there are “marriage penalties” in the tax law, and a couple can be declared ineligible for welfare because of the combined income of the two partners. That is, there are government policies and procedures that lower the incentive for low-income couples to enter into a formal marital arrangement. Often, women work because their financial circumstances make it necessary to have two parents’ incomes to provide for and protect their children adequately. Laws regulating welfare, and marriage and economic conditions, are only two of many possible external contexts that affect family behavior and family change.

Confounding of Family Diversity and Family Decline. Finally, we are concerned about an unfortunate slippage in discussions of family decline, in which the indicators of greatest concern (e.g., single parenthood, poverty) are associated with changes that have taken place with more frequency in members of minority groups, especially minority groups who are also experiencing economic hardship. It turns out, then, that policies suggested to remedy the ills of family decline (e.g., marriage promotion) are often directed at low-income minority groups, without recognition of the fact that in sheer numbers, the social indicators of concern occur more frequently in European American families and that they occur across the whole socioeconomic spectrum.

Problems with the Family Resilience Interpretation

Our conclusion from the fact that the family decline arguments are seriously flawed is not that the family resilience interpretation is the correct one. Writers advancing the family resilience view often criticize the family decline theories for focusing only on family structure (married or not, divorced or not), when it is the quality of family relationships that determines the developmental course of adaptation or psychopathology. Countering this argument, some authors point out that studies with careful statistical controls for income show reduced links between divorce or single parenthood and negative effects for children, but the associations are not eliminated completely (Cherlin, Chase-Lansdale, & McRae, 1998; Furstenberg & Kiernan, 2001). Similarly, to state that divorce has long-term effects

in “only” 20% of children risks minimizing a significant and important social problem. The fact that 40% to 50% of contemporary couples who marry will divorce indicates that there are serious difficulties in maintaining adult intimate relationships over time.

We agree with Cherlin and Furstenberg (Cherlin et al., 1998; Furstenberg & Cherlin, 1991), family sociologists who conclude that historical increases in divorce, cohabitation, and single parenthood have brought with them the potential for increased risks for children’s development—by their nature or because they bring with them other potentially disruptive changes, especially poverty. We also agree with Amato (2000), a family sociologist whom we quoted earlier, who suggests that it is necessary to ask more differentiated questions about who will benefit and who will suffer when family changes and transitions occur.

A Developmental Psychopathology Perspective on Resolving the Debate

We raised the question of whether family change should be equated with family decline. Our answer is yes and no. On one hand, it would be foolhardy for researchers, clinicians, and policymakers to ignore the possibility that there are some special challenges involved in raising a child in divorced and single-parent families. On the other hand, we must recognize the fact that nontraditional family structures do not account for the vast majority of diagnosable problems in children, adolescents, and adults. Clearly, it is necessary to identify the strengths in nontraditional families that lead most of the children who live in them to meet the academic and social challenges that life imposes, just as we try to understand what is operating in traditional families when children in two-parent families succumb to diagnosable pathology.

A synthesis of the family decline and family resilience perspectives is entirely consistent with the assumptions of developmental psychopathology that we described earlier. First, it is necessary to acknowledge that some family structures are associated with higher risks for adaptation than others, while noting that (1) higher risks do not automatically mean higher levels of distress, (2) lower-risk families are not problem-free, and (3) the majority of members of families in any of the structures we have described are functioning outside the realm of what is considered psychopathology.

Second, family structure represents a static picture of the family at a point in time. Families often go through multiple transitions simultaneously or in quick succession, and it is often the disequilibrium associated with the transition (e.g., moving house, drops in income, single parent-

hood, the birth of new children) rather than the end point (e.g., divorce) that plays a causal role in the adults' and children's adaptation (G. R. Patterson & Capaldi, 1991).

The issue, then, is not whether family decline or family resilience views of historical family change are correct. Both views have implications for our understanding of developmental psychopathology. As family decline proponents have framed the discussion, psychopathology and resilience are located in some family forms *by definition*. In a view more consistent with the principles of developmental psychopathology, we conclude that (1) U.S. families are becoming more diverse, (2) more families are moving toward nontraditional family structures, (3) some nontraditional families are having difficulties coping with the demands of raising children, and (4) a substantial number of families with more traditional family structures are having similar difficulties in personal adjustment, establishing satisfying family relationships, and coping with the challenges and demands of life outside the family.

Expanding Considerations of Family Diversity: Meeting the Challenge of Understanding Contemporary Families

How is the field of developmental psychopathology responding to the changes in family life that all observers agree have occurred? Our conclusion is that there is a fundamental gap in the research on developmental psychopathology, in which the research questions have not caught up to the realities of life in families. Despite some promising beginnings, we still know very little about differences in models of risk-protection-outcome in different populations. This is a critically important question not only for theories of developmental psychopathology, but also for the targeting of interventions directed toward reducing the family risk factors and increasing the family protective factors associated with specific problems and disorders. There is also a critical gap in the family intervention literature. Although a number of family theorists and clinicians argue that family theory and therapy practice need to pay attention to the diversity of families, and reject the idea that "one [intervention] size fits all," few if any of the creative modifications suggested to meet the needs of diverse populations have been subjected to rigorous evaluation.

Gender

We have noted that there are marked gender differences in the incidence of some types of psychopathology (e.g., depression, externalizing) and that there may be gender dif-

ferences in family risk patterns for these disorders, with depression more likely to be associated with difficulties in mother-daughter relationships and aggression more likely to be associated with difficulties in fathers' relationships with both daughters and sons (P. A. Cowan, Cowan, Ablow, Johnson, & Measelle, 2005). We have also noted that there appear to be gender differences in the way men and women deal with conflict and disagreement in their relationship as couples. The need to create more complex theoretical family models of psychopathology that take gender into account has been noted by the feminist critics of traditional family therapy (discussed earlier) and has begun to occur in family therapies (T. S. Zimmerman, 2001), but investigating differences in connections among fathers, mothers, sons, and daughters has not been a central focus of family research.

Age

Despite the fact that marriages are occurring later in life, and childbirth is extending to mothers in their early 40s and beyond, almost all of the contemporary research on couples, especially investigations that use observations of marital discussions, is based on couples between age 20 and 40. We know very little from direct observations about marriages of older couples (but see Charles & Carstensen, 2002; Levenson, Carstensen, & Gottman, 1994), except that they tend to express more positive emotion than younger couples do when they discuss a disagreement. This finding may be attributable in part to the fact that studies of older couples are more likely to include spouses with positive relationships that have withstood the test of time, but increased positivity could also come from the perspective that age brings or from a lessening of stresses associated with early careers and the rearing of young children.

Two sets of questions about age relevant to developmental psychopathology remain to be answered. First, are the models of risk factors that have been established for parents who have their first child in their 20s different from models for families in which parents are in their late 30s or mid-40s? For example, analyses of our own data (C. P. Cowan & Cowan, 2000) indicate that marital satisfaction declines more after the birth of a first child for couples in their 30s than for couples in their 20s. We know of no data that address whether the risk of decline increases for samples of 40-year-old parents of young children.

Second, older parent-adult child relationships are rarely studied (Ryff & Seltzer, 1996), and there is almost no information based on direct observation of couples or observations of parents with their adult children. Are the risk factor models that account for distress and the protective

factors that reduce distress in older parent-child relationships different from models established in studies of younger couples? For example, does marital conflict and marital withdrawal in older couples have the same negative impact on their adult children that we have seen with couples with young children and adolescents? Also, outside of the assumption that children tend to become more autonomous and independent in late adolescence in Western industrialized societies (Bowen, 1978), we are not aware of family system theories suggesting that family process qualities change with the age of the participants. In other words, neither theory nor research on developmental psychopathology provide much of a *developmental* perspective on the links between family functioning and adaptation in clinical or nonclinical families. Especially given the longer life span of modern adults, it seems important to seek answers to these questions if we are to understand the emergence of psychopathology throughout the life span.

Income

We are struck by the fact that, although information and concern about low-income families exists in the form of thousands of studies and reports, there have been few systematically tested income-based interventions for this group (for an exception, see Gennetian, Knox, & Miller, 2000). Virtually all studies of couples therapy and early interventions for couples are composed of middle-class, primarily European American participants (Dion, Devaney, McConnell, Hill, & Winston, 2003). Family therapies have sometimes targeted low-income families, but almost always with a focus on minority status rather than low income (Robbins, Schwartz, & Szapocznik, 2004; Robbins et al., 2003; Szapocznik et al., 2004). We have a great deal to learn about whether and how couple and family interventions require modification in order to address the needs of families in different economic circumstances.

Ethnicity⁵

In the 1970s, a book reviewing research across all fields of psychology was entitled *Even the Rat Was White* (Guthrie,

1976). Over the past 3 decades, it has been encouraging to find a number of researchers studying families of color (e.g., Brody & Flor, 1996; Coll, Meyer, & Brillion, 1995; McLoyd, 1990; Parke & Buriel, 1998), describing mental health issues unique to each ethnic group (e.g., Serafica, 1990), and proposing necessary modifications of family therapies to create more culturally sensitive interventions that fit the beliefs and practices of ethnic minority families (e.g., McGoldrick, Giordano, & Pearce, 1996). As examples, we focus here on three major ethnic subgroupings: African American, Asian American, and Latino families. We recognize that there are many other subcultures in the United States and many other ethnic groups across the world, and that there are important variations within each of these subgroupings that we do not have the space to describe in adequate detail.

Research on Cultural Differences and Similarities.

In the early years of research on minority mental health, almost all studies involved comparisons of one or more minority groups with Caucasian samples, with concepts and measures developed on middle-class Whites applied to minority participants (an “etic” approach). This research strategy led to an emphasis on differences that were interpreted as problems and deficits in the minority groups (Jones & Korchin, 1982). By contrast, most current writers have adopted an *emic* approach, which attempts to describe both strengths and vulnerabilities of individuals, families, and cultural institutions from the perspective of members of a specific group.

In reading a number of descriptions of minority families from within their own cultural perspective (e.g., McGoldrick et al., 1996), we were struck by the fact that over and above obvious uniqueness, there were a number of similarities among the accounts of different groups. Attempts to understand African American, Latino, and Asian American families typically begin with a history of the circumstances of their emigration (voluntary or forced) to the United States and, especially for Latino and Asian families, an account of differences between generations, depending on whether they immigrated as adults or children, or on whether they are first-, second-, or later-generation citizens. To different degrees and in different ways, all three groups have experienced racism, discrimination, unemployment, and poverty, some in their countries of origin, and most at some time in the United States or other country of destination. Families in all three groups are more likely than European Americans to be church-affiliated or influenced by religious beliefs, though this may be changing

⁵ We do not have space here to deal with the complex issues involved in describing individuals and families in terms of ethnicity, race, culture, and minority status. We are aware that race is a social construction (Smedley & Smedley, 2005), ethnicity is unclear as a designation, and minority status is a relative term depending on the demographics of the territory being discussed. Here we use the terms “ethnic group” and “minority group” interchangeably, with the understanding that each of these terms has unresolved ambiguities.

(Wilcox, 2004). One salient dimension in the lives of each group is the importance of family and extended kin networks, with grandparents centrally involved in the rearing of young children together with parents or in parents' absence due to work or other circumstances (Burton & Stack, 1993; Goodman & Silverstein, 2002; Strom et al., 1999).

One cultural influence on family cohesion is centrally important in thinking about psychopathology and family treatment. Especially in Latino and Asian American families in comparison with European American families, there is a high value on connectedness and a lower value on individuation from the nuclear and extended family as adolescents make the transition to adulthood. Current generations of teenagers and young adults struggle with the tension this creates between the two worlds (Falicov, 1996; Hines & Boyd-Franklin, 1996; Matsui, 1996). A second important influence on both the incidence and prevalence of psychopathology and the utilization of mental health services comes in the cultural shaping of beliefs about mental illness. For example, both Latino (Contreras, Fernandez, Malcarne, Ingram, & Vaccarino, 2004) and Asian (Mak & Zane, 2004) beliefs about depression focus more on physical characteristics and less on emotions so that symptom reporting by individuals and family members differs in different cultures. Third, partly on the basis of practices in their country/culture of origin, and partly based on experiences with health and mental health delivery in the United States, all three groups tend to turn elsewhere for help with family members' emotional problems and are often skeptical about whether therapeutic services offered to minority families will meet their need (e.g., Boyd-Franklin, 2003).

Finally, although the content is often different, family members in all ethnic minority groups struggle with issues of (at least) dual identities: Who am I as a Latino, Asian, Black man or woman? Who am I as an American? And how do those identities fit together? In part, this is an issue of acculturation and so may vary with the length of stay in the host country (Tsai, Ying, & Lee, 2000). These issues often place second- and third-generation children and adolescents familiar with European American family practices at odds with their parents and grandparents, and this may lead to behaviors considered problematic or dysfunctional by the families or others in the community (teachers, mental health professionals).

Having focused on similarities among ethnic minority groups in thinking about how culture can affect psychopathology, it is important to acknowledge the obvious differences. The immigration experiences of African Americans are more likely to have occurred in the past, some under

forced conditions of slavery, whereas some Latino and Asian American communities are in a state of fluctuation now due to recent immigration. There are differences in language and literacy, achievement patterns, religious affiliations, marriage and divorce practices, and possibly patterns of emotion regulation in close relationships. It seems reasonable to assume that there are modal differences among ethnic groups in the prevalence of the family risk factors that have been linked with developmental psychopathology in European American families.

Despite the welcome interest in ethnicity and families, a central dilemma remains for the understanding of developmental psychopathology. There is still a dearth of systematic study of how patterns of risk factors may differ from one cultural group to another. The few studies we are aware of that focus on risk-outcome patterns suggest that, despite differences in the prevalence of some very important risk factors such as poverty, family risk models operate similarly across groups. For example, reviews of research by McLoyd and her colleagues (McLoyd, 1990; Mistry, Vandewater, Huston, & McLoyd, 2002) suggest that poverty in African American families has negative effects on children's adaptation because it disrupts family relationships in much the same way that Conger and his colleagues (1994) described for low-income European American farm families. A similar approach to comparisons between Mexican American and European American low-income families (Parke et al., 2004) finds that the same list of family factors (economic stress, parental depression, marital problems, hostile parenting) accounts for variations in children's adaptation or psychopathology, although there are two interesting differences. The primary predictors of children's adjustment problems were marital problems for Mexican American couples and hostile parenting for European American fathers. Acculturation also played a role in the links between family functioning and psychopathology in the Mexican American families: Mothers who were more integrated into the Anglo culture were likely to be less hostile as parents, but more likely to report conflictful marriages.

It is too early, of course, to accept these two studies as proof that there are similarities with variations in risk-outcome patterns among ethnic minority and European American families. It does lead us to expect that among the needed new studies, at least some will find commonalities that may generalize across an even wider range of ethnic groups. For example, new studies of interventions with refugees in African, Asian, and South American countries and in the United States (K. E. Miller & Rasco, 2004) point

to the importance of family factors in postimmigration adjustment, especially when the circumstances of migration result in the disruption of family ties. Rasco and Miller (2004) summarize studies of immigrant families using a multidomain risk model that suggests the need for more systemic research on the way political violence and geographic displacement affect individuals, families, and communities, and a cautionary note that these models may show both similarities and differences in different ethnic communities facing different sets of circumstances.

Culturally Sensitive Interventions. It would be unreasonable to expect family therapists to wait until risk models for each ethnic group have been tested before considering how they can become more sensitive to cultural variations in families. Some edited books present separate chapters with descriptions of different ethnic/racial subgroups (Ancis, 2004; Ho, Rasheed, & Rasheed, 2004; McGoldrick et al., 1996). Other authors avoid a comparative approach by focusing on specific approaches to African American (Boyd-Franklin, 2003), Asian American (Jung, 1998; Ng, 1999), or Latino (Falicov, 1998; Flores & Carey, 2000) families.

Each of these works describes the historical, cultural, and political context leading to prejudice, discrimination, and oppression of minorities, the characteristic ways that families within each group are organized, the perceptions of majority cultures and institutions that may make it difficult for the families to utilize existing mental health services, and the special issues and challenges that families within each group may face. The authors, primarily clinicians, tend to focus on issues of language and inability to communicate with the English-speaking majority, loss due to immigration and social disruption, pressures to assimilate rather than adopt a bicultural stance, the obligation of deference to elders in Asian families, and distrust between males and females and the prevalence of single parenthood in African American families. All of this information is designed to provide a contextual definition of what is normal and abnormal from the perspective of a specific ethnic group. One goal of these authors is to make certain that the standards and values involved in the assessment of deviance, which are inevitably involved in the definition of psychopathology, are made more relevant to the culture of the minority. A second goal is to identify therapy practices that are more acceptable and helpful to family members in each group.

We do not yet know whether the attempts to make interventions more relevant to each target population produce

benefits for participants, over and above the usefulness of more traditional therapies. Clinicians involved in these pioneering attempts would be correct to argue that it is necessary first to develop new interventions and to rely on in-depth qualitative analyses of their strengths and weaknesses before larger scale clinical trials are designed. This is a necessary first step in any clinical-scientific intervention endeavor. Our aim here is to point out that, especially in a health delivery system context in which validated treatments are more often demanded before program support is given and insurance reimbursements are approved, it is time to embark on more concerted validation efforts of the new approaches that have been created (see Pinsoff & Wynne, 2000).

Nontraditional Families

The research issues concerning family factors in psychopathology in families with gay or lesbian parents are similar to the ones we have discussed for families grouped on the basis of age, income, or ethnicity. We cited research that reveals few differences in adaptation between the children of gay or lesbian parents and those of heterosexual parents. However, questions about similarities and differences in patterns of risk have mostly been left unanswered. An exception is a set of studies showing that the risk models that predict distress in heterosexual couple relationships can be applied equally well to gay and lesbian relationships (J. M. Gottman et al., 2003). We are not aware of research that attempts to link personal distress, couple relationship distress, and parenting style with child outcomes in gay and lesbian parent families, so we do not know whether modifications of existing risk models are required for families with gay and lesbian parents. There have been some recent descriptions of specific issues and therapy approaches to working with gay and lesbian families (Laird, 2003; Laird & Green, 1996; Malley, 2002; Malley & McCann, 2002; Pachankis & Goldfried, 2004; Yarhouse, 2003). Like the writing on family therapy with minority families, this work presents a contextual analysis of special issues faced by gay and lesbian families because of legal, political, and social stigmatization and because most of these families have no examples from prior generations of how families with two same-sex parents function most effectively.

Reading case studies in books and articles in family therapy, we conclude that much of what is currently described as family therapy occurs with a single parent and one or more children. As in many of the other variations we discuss here, there is evidence of higher risk in these families, but no evidence yet to show that the family risk models

would differ in different family structures. We have not found any relatively recent books for therapists and only a few articles that go beyond case studies to provide guidelines for treating single parents and their children (Anderson, 2003; Everett & Everett, 2000; Jung, 1996). It is not clear, then, whether new models of family therapy are needed to treat troubled parents or children in this large population.

This survey suggests that there are many sources that family therapists can consult to consider how their practices can meet the challenges of the diversity of contemporary families. Most of these sources refer to the available research on diverse families. However, we are alarmed by the fact that, with the exception of the prevention programs targeting family transitions, none has provided systematic research evidence that (1) the interventions they propose actually work, (2) the modifications they propose function as mechanisms of change, or (3) the therapies provide benefits over and above traditional family therapy approaches.

Family psychopathology researchers and therapists face a dilemma when they attempt to meet the challenges of family diversity. At one extreme, early family systems theories implied that universal system principles, relatively unmodified, could guide the treatment of all families. At the other extreme is the argument that family treatments must be adapted to be appropriate for each demographic group. To follow Tolstoy's (1899, p. 1) dictum to its logical conclusions—"Happy families are all alike; every unhappy family is unhappy in its own way"—therapists could be faced with the task of creating unique therapies for each family. Imagine the complexity of considering even a limited number of variations and trying to develop family therapies specifically targeted to older and younger European American, Asian American, African American, and Latino families in which parents are cohabiting, married, separated, or divorced, native or immigrant, and so on. Even with this specificity, it would be necessary to expand the variations to include other subcultures within the United States and other cultures across the world. Furthermore, it is necessary to remember that individuals and families *within* each category show wide variability in terms of family beliefs, practices, behavior, and adaptation. One cannot simply assume that a particular older Chinese American couple, or an unmarried teen European American couple, or a Latino stepfamily actually display the modal characteristics typical of the group they identify with (Demo et al., 2000).

In the absence of specific risk-outcome models and validated treatment models for specific types of families, what are family therapists to do? In our view, the ideal solution

involves a balance of universality and particularity. Clinicians who conduct assessments and therapists who work with family members need to be aware of common principles that can be applied broadly across many different types of families, while staying attuned to the unique features of each family's needs and concerns, some of which may be related to their particular cultural background.

FAMILY RESEARCH AND FAMILY POLICY

Family policy—decisions made by legislative and executive branches of government to regulate and enhance the well-being of families and allocate scarce resources—covers a wide array of topics, including contraception, abortion, marriage and divorce, child support, adoption, family leave, health and mental health, welfare, child labor, the justice systems (adult and juvenile), child care, domestic violence, and child abuse (Sealand, 2003; S. L. Zimmerman, 2001). By designating some families as in need of help, family policy helps to determine what is defined as pathology. At the same time, research on families and psychopathology is often cited in discussions concerning laws, regulations, and service delivery systems.

The links between research-clinical findings and policy are tenuous at best, for three main reasons. First, many policy decisions are made on moral or value grounds, and these grounds are held to provide a sufficient *political* justification for choosing a course of action. Despite the reliance on data by some political advocates and social scientists, research findings are often considered irrelevant to public debate. Second, research conclusions and policy proposals are framed in different languages. Policymakers are trying to find universal rules and solutions to societal problems. They want to know whether their proposed solutions will work for the largest number of citizens. They seek yes-or-no answers to specific questions. By contrast, risk researchers are used to working with probabilities and individual differences. Their answer to a question about whether a plan of action will work is often "It depends; it will for some and not for others." Given these different approaches to the nature of the discourse, it is almost inevitable that policymakers and family researchers and clinicians wind up talking past each other, with neither group benefiting from what the other has to offer. Third, as we have seen, research on hot issues having to do with understanding psychopathology almost always results in disputed interpretations. Researchers are often as divided on family issues as politicians are, and are not immune to the value biases that create controversies in the public or polit-

ical arena. To illustrate the interplay of family policy and family research on psychopathology, we briefly mention three topics that are currently at issue and likely to be central issues for some time to come.

Father Involvement

Over the past 30 years, societal concern about the negative impact of absent fathers on their children's development stimulated efforts to design interventions that would encourage fathers to take a more active, positive role in their children's daily lives (Mincy & Pouncy, 2002). Research on the definition of father involvement, the consequences of father involvement, and the factors that encourage or discourage father involvement (Tamis-LeMonda & Cabrera, 2002) has led to multidomain risk-outcome models similar to those we have described throughout this chapter. In contrast to political arguments that father involvement is a matter of the motivation and will power of individual fathers (Blankenhorn, 1995), the research suggests that whether or not fathers take an active hands-on role in the daily lives of their children is a complex outcome of a variety of factors, including demographic and psychological characteristics of individual fathers, the quality of their relationship with the mother of their children, intergenerational patterns, and outside-the-family supports for and barriers to men becoming more involved (Tamis-LeMonda & Cabrera, 2002).

Our own summary of the research and intervention literatures (P. A. Cowan & Cowan, 2004) notes a remarkable disconnection between research on father involvement and programs to promote father involvement, just as we see in the family psychopathology field in general. A few program designers draw on risk factor research but rarely provide systematic evaluations of outcomes or mechanisms that would reveal whether targeting the hypothesized risk factors and change mechanisms actually produces the desired change in psychopathology.

We are currently involved as part of a team with Marsha Kline Pruett and Kyle Pruett of Yale University in the Supporting Father Involvement Project, sponsored by the California Office of Child Abuse Prevention. The project evaluates variations of interventions in four California communities with a large proportion of low-income White and Hispanic families. The design of this randomized clinical trial contrasts participation of fathers and their partners in (1) a 16-week fathers group, (2) a 16-week couples group, and (3) a one-time information session about the importance of father involvement (the control condition). The decision to contrast these two styles of ongoing interven-

tion was based in part on research showing that the single best predictor of fathers' involvement with their young children is the quality of their relationship with the child's mother (Bouchard & Lee, 2000; Cohen, 2001; Frosch, Mangelsdorf, & McHale, 2000). Outcome data are in the process of being gathered as this chapter goes to press.

Strengthening Marriage: Strengthening Couple Relationships

Two research studies, one involving the gathering of new data and one involving a survey of the literature, have played important roles in discussions of policy related to low-income unmarried couples. The policy issues are based on a moral concern by some about the high rate of divorce and single parenthood, and a financial concern by others that these families are likely to be poor and their children to have higher rates of problems than children in two-parent families. First, the Fragile Families Study of hospital births in 20 American cities (Carlson & McLanahan, 2002b; McLanahan, 2002; McLanahan et al., 1998) found that around the time of childbirth, more than 80% of the biological fathers were involved in a romantic relationship with the child's mother, and 50% of the couples were living together. Contrary to popular belief, interviews with the couples showed that most of them hope to get married. The "magic moment" around the birth of the baby dissipated somewhat, so that over the next year, 58% of the fathers were still in romantic relationships, mostly those who had been living with the mother when the child was born. Second, an influential book, *The Case for Marriage: Why Married People Are Happier, Healthier, and Better Off Financially* (Waite & Gallagher, 2000), was used to support the argument that if women and children in unmarried families are at risk, then a wise policy alternative is to encourage them to marry. We have discussed elsewhere the frequently ignored fact that correlations do not (should not) prove causal connections and are not adequate to provide support for policy decisions.

In part resulting from a moral concern, and in part using data from these two works as a justification, the U.S. Administration for Children and Families awarded two contracts to research and evaluation agencies for randomized control trials of interventions for unmarried low-income couples making the transition to parenthood (Building Strong Families, administered by Mathematica), and low-income married couples with and without children (Strengthening Healthy Marriages, administered by Manpower Development Research Corporation [MDRC]), to work toward healthy couple relationships and marriages.

Not surprisingly, discussions of these initiatives have generated some public disagreements. Because federal financial support for strengthening couple relationships is novel, the results of these randomized controlled studies of interventions addressed to couples' issues in low-income communities may provide important information about how low-income partners struggle with issues in their lives as couples and whether it is possible to design interventions that make those struggles more manageable.

Welfare Reform

In 1996, President Clinton signed a bill that promised to "end welfare as we know it," in part by requiring women on welfare to work outside the home, and in part by limiting the time they could spend on welfare (see DeParle, 2004, for a fascinating account of the antecedents and consequences of the legislation). Arguments about why this bill would enhance the lives of families were based in part on the assumption that parents' work provides both psychological and financial benefits to the parent and the child. This policy was undertaken without social science research to provide a justification. Evaluation of welfare reform is now in progress; clearly, it has reduced the numbers of families on welfare and the costs associated with welfare programs. Studies of the impact on men, women, and children who move off, or who are forced off, the welfare rolls is still in progress (Chase-Lansdale et al., 2003; Fuller, Kagan, Loeb, Carroll, & Growing Up in Poverty Project, 2002).

These are only three examples of the complex and uneasy intersection of family research and family policy. We are optimistic about the fact that there seems to be a growing tendency at the federal level to encourage, and even fund, systematic evaluations of new policies and programs related to families. We are less optimistic about the tenor of public and academic debate in which research findings are cited in support of one position while ignoring the complexity of drawing conclusions from a welter of conflicting or incomplete evidence. Nevertheless, we believe that attempting to bring systematic evidence from social science into discussions of family policy has the potential for creating more differentiated and nuanced perspectives on the diversity of families for policymakers and social scientists alike.

FUTURE DIRECTIONS

Throughout this chapter, we have attempted to include suggestions about where the field is and should be going. In

this final section, we summarize several salient points to highlight what we see as important next steps:

1. *Addressing the diversity of families.* We need investigations of a wider range of risk models for different populations, and evaluations of attempts to modify family therapies to fit the needs of these populations, while preserving generic principles that may work across contexts.

2. *Addressing the diversity of theories.* We have suggested that ideas from family systems and family risk factor approaches are becoming more integrated in clinical work with families. The movement toward the integration of these approaches in research on understanding developmental psychopathology appears to be proceeding more slowly, although there are some indications of movement toward a synthesis of views in this area as well. One indication of the lack of integration in both research and practice is that systematic diagnostic systems for describing the psychopathology of *families* have been slow to develop (Kaslow, 1996). A second arena in which these two approaches remain separate is in family risk researchers' tests of *linear* causal risk models, in which they combine measures of family relationships as independent variables in accounting for variations in the functioning of identified patients—despite family systems' assumptions about bidirectional causality.

In our view, integrations of the multiple perspectives we have outlined here have some way to go. The six-domain family model summarizes the key aspects of family life in which individuals and dyads move toward or away from adaptation. The nine-cell matrix provides a checklist of alternative explanations of stability and change within each of the domains. At some point, family researchers and clinicians must accept the fact that the etiology of both individual and family psychopathology involves combinations of internal, external, and interactive factors that operate at biological, psychological, and social levels of a system.

3. *Explaining risk-outcome linkages.* Perhaps the main difference between research studies cited in this chapter and those in the chapter on family systems and developmental psychopathology in the previous edition of this volume (Wagner & Reiss, 1995) is the vast increase in research on mechanisms to explain *how* risks are connected with developmental psychopathology outcomes. The search for mediators and moderators has become something of an obsession, and despite Baron and Kenny's (1986) often-cited attempt to distinguish between them, there continues to be confusion on this point. Mediators account for existing correlations, for example, when the correlation between maternal depression and children's aggression can be explained by the fact that depressed women are more likely to

be in conflictful marriages (N. B. Miller et al., 1993). Moderators are markers of conditions that change the links between risks and outcomes, as, for example, in any finding that shows significantly different patterns for different groups such as boys or girls, or parents with high or low marital conflict.

The identification of both mediators and moderators is essential for family therapists. Learning about modifiable mediators—family process mechanisms linking risks and outcome that can be changed—could help clinicians increase the effectiveness of their interventions. Learning about modifiable moderators—family process mechanisms that increase protective factors or reduce vulnerabilities—could also identify conditions that protect family members from the negative effects of risks that cannot be modified.

4. Putting the development back in developmental psychopathology. We know that there are systematic variations in the age of onset of many disorders, such as the risks of externalizing, internalizing, and Schizophrenia that emerge in adolescence. In part restricted by the ubiquity of the *DSM*, developmental psychopathology has not yet become fully developmental. Too many categories like depression and Schizophrenia have the same diagnostic criteria for children and adults, when it is absurd to think that 7-, 17-, and 70-year-old depressed persons have the same underlying disorder. Once a person enters a category, there may be a developmental course of the mental illness and a lawful, systematic change in both its structure and function over time. We believe that these are important lines of inquiry for developmental psychopathologists in the next decade.

5. More effort directed toward empirically validated treatments. There has been increased pressure by research funding agencies, service delivery systems, and insurance companies to rely on evidence-based therapies, and decreased support of approaches that have not been validated in systematic studies. The outgoing editor of *Family Process* (Anderson, 2003, p. 323) noted the profound gap between those who create solid research studies and “clinicians [who] tell me that they neither read nor value the research data being produced and that they basically fail to see any relationship it has to the realities of their practice.”

There is an important distinction to be made between “empirically validated treatments” and “evidence-based treatments” (Messer, 2004; J. E. Patterson, Miller, Carnes, & Wilson, 2004). Family therapists need to have more in their armamentarium than a list of “valid” therapies, especially when there is such a diversity of families and a dearth of large-scale tests of efficacy and effectiveness of a specific therapy for a specific group. Nevertheless, thera-

pists have two obligations. The first is to read and evaluate the literature to inform their understanding of risk-outcome models of psychopathology and to learn whether certain treatment approaches have received empirical support. The second is to provide systematic information on the course of each treatment in the form of process notes, questionnaires, or audiotaped or videotaped observations that attempt to determine whether families improve after a course of treatment and which characteristics of client, therapist, and their interaction appear to be associated with positive and negative outcomes.

A Final Word

We believe that this is an opportune time for researchers and clinicians eager to grapple with a family systems or family risk factors perspective on developmental psychopathology. The field now has a solid 50-year history in which there has been a remarkable unfolding of creative ideas about how to think about both mental health and mental illness in a family context. An increasing quantity and quality of systematic research studies has provided a solid empirical foundation for models of risk-outcome linkage and therapeutic and preventive intervention. And yet, there is almost endless opportunity to make important contributions to this field—by modifying existing theories to fit the increasing diversity of family life, by testing risk-outcome models in as yet untested diagnostic groups and cultural settings, and by developing new and even more complex models of how family structures and processes are linked with adaptive and maladaptive functioning inside and outside the nuclear family. It is our hope that contemporary family researchers and clinicians will rise to meet the challenge of expanding our understanding of the family context of developmental psychopathology as the field moves into the next 50 years.

To more deeply understand the role of culture in the emergence, persistence, and desistance of psychopathology among children and youth, this chapter examines cultural diversity in child and adolescent psychopathology and its development. Based on a selective review of recent comparative studies, we present a synthesis of cross-cultural and ethnic differences that stood out amid the similarities also found. We examine culture's role in child psychopathology and its development through an examination of cultural diversity. Our specific aims are (1) to review and synthesize the findings of recent comparative studies that examined cultural variations in the expression of symptomatology, prevalence, development, and correlates of psychopathology in children and adolescents; (2) to report related findings from ethnic and cultural studies that sampled only one population; (3) to identify conceptual and methodological issues identified in the studies reviewed; and (4) to suggest future directions for research.

A DEVELOPMENTAL-CONTEXTUAL PERSPECTIVE ON PSYCHOPATHOLOGY

The developmental approach to psychopathology, more commonly known as developmental psychopathology, asserts that because there is unity in development, the study of psychopathology or development gone awry in infants, children, and adolescents has to be based on knowledge of normal development and should involve the application of developmental principles. A corollary to this assertion is that research on development gone awry can enhance our understanding of normal development. Therefore, the field of developmental psychopathology focuses on the interplay between normal and abnormal development and on the relationship between deviant and typical forms of a behavior. Like other attempts to describe and explain psychopathology, the developmental approach seeks to understand the etiology, course, and prognosis of a specific

disorder. However, its interests extend beyond the identification of predisposing, precipitating, and maintaining factors or risk and protective variables. This approach also seeks to ascertain the internal and external factors that promote competency and resiliency in individuals. Most important, the developmental approach is concerned with describing the developmental sequence of a particular disorder and understanding the processes as well as mechanisms involved. Consistent with a transactional model of the developmental process, the emergence of psychopathology is conceptualized as occurring through a dynamic transaction with intra- and extraorganismic forces (Cicchetti & Cohen, 1995). Acknowledging these forces implies that developmental psychopathology views deviant behavior in context. Thus, it is congruent with a developmental-contextual perspective. Contexts vary; they may be intraorganismic or extraorganismic. An intraorganismic context is organic, involving biologically based characteristics (e.g., genes, brain, central nervous system) and an intrapersonal context involving personal characteristics (e.g., cognitions, emotions, personality). An extraorganismic context subsumes an interpersonal context involving social interactions and relationships (e.g., family, peers) and a superordinate context comprising variables that deal with aggregates of individuals taken as a unit (e.g., ethnic group, social class, culture; Wenar & Kerig, 2000). These different contexts may be considered separately for purposes of analysis, but they are really interrelated (Lerner, 1995). The focus of this chapter is on one type of superordinate context, namely, culture. A cultural perspective to developmental psychopathology necessitates that normal and abnormal development as well as typical and deviant forms of behavior be considered from the standpoint of both dominant mainstream culture and the minority cultures. A developmental-contextual approach is compatible with this perspective.

CULTURE

Culture refers to the designs for living in a specific habitat that have evolved among a particular group of people and are transmitted within and between generations (M. Cole & Cole, 2004). It refers to the entire way of life of a society including its values, beliefs, attitudes, norms, practices, language, religion, and institutions. These designs for living are represented through artifacts, actions, or symbols. North's (1990, p. 37) definition of culture as "a language-based conceptual framework for encoding and interpreting information that the senses are presenting to the brain" em-

phasizes its symbolic nature. There is shared meaning among those who have the same culture. Their view of the world and its people and how they think and make judgments in general or specific areas of life are filtered through a culturally based information system (Goode-nough, 1989).

The term "culture" is usually employed to designate the designs for living among individuals who, frequently but not always, share a common biological ancestry and, initially occupied a particular habitat, namely, an ethnic group. It is in this sense that the term is used in this chapter, though it is acknowledged that the term may also be extended to the values, beliefs, attitudes, norms, and practices common to members of a distinctive group identifiable through a shared characteristic such as gender, social class, sexual orientation, religion, or profession.

Assumptions about Culture

Assumptions about culture have implications for both the research enterprise itself and the applications of research findings.

Culture has an ecological context. The designs for living that constitute an ethnic group's culture are assumed to have evolved because they facilitated adaptation to the group's habitat at a particular time. Thus, the origins of an ethnic group's designs for living and their functions are tied to specific spatial, social, and temporal contexts. This implies that the adaptive value of a specific design for living is relative to context.

At any given time and context, cultural practices are likely to differ in their adaptive value and those that remain prominent in an ethnic group's cultural repertoire may not necessarily be the ones with optimal value for adaptation. It is therefore important to assess the current adaptive value of a cultural belief or practice in its contemporary context. Earlier, social scientists assumed that the cultural values, beliefs, and practices that survive are those that are optimally effective in facilitating adaptation. Contemporary researchers have challenged this assumption. According to Ellen (1982, p. 251), "Cultural adaptations are seldom the best of all possible solutions and never entirely rational." Using recent findings from cognitive science to bolster his contentions, Edgerton (2000) also argued that traditional beliefs and practices may persist not because they are optimally beneficial but because they generally may work well enough without further changes; they are retained in the cultural repertoire because they require the least effort and involve minimal risk. He also cautioned behavioral and social scientists

about assuming that any persistent traditional belief or practice in a surviving society must be adaptive. It would be more prudent to assume, he contended, that there is a continuum of adaptive value along which any belief or practice may fall anywhere. A belief or practice may simply be neutral or tolerable, or it may be beneficial to some members of a society while harming others, and sometimes it may even harm everyone.

Culture persists, transmitted from one generation to the next, but the adaptive value of specific cultural variables may change over time. Initially, it was assumed that the designs for living that make up culture persist because their ecological effectiveness is constant across time and space (Campbell, 1975; Harris, 1960; Kluckhohn & Leighton, 1962). However, contexts change over time and, consequently, the adaptive values of cultural beliefs and practices, even those that were optimally effective at one time, may also shift.

Culture is dynamic rather than static. Previous conceptualizations of culture assumed that it remains static as it is passed on intra- and intergenerationally. However, the nature of individuals and contexts changes over time, and culture becomes modified accordingly. Cultural practices can be altered within a generation, as evidenced by recent changes in American food preferences, or modified across generations. Even when an ethnic group remains in the same geographic context over time, changes can come about through the transactions of the group's members with one another or with members of other ethnic groups and with changes in the physical, social, and technological environments. Changes in the physical environment might necessitate modifications in the means of livelihood and, consequently, in the associated cultural practices. For example, in some areas of the world, polluted waters have made fishing a less lucrative source of income, thus necessitating an occupational change that may, in turn, result in modifications of certain cultural practices that evolved from a fishing economy.

Culture is mediated through social interactions. Initially, this occurs through the parent-child relationship and subsequently through other interpersonal transactions taking place in various ecological systems (Bronfenbrenner, 1977, 1979). Transmission occurs through both verbal and nonverbal modes of communications, directly and indirectly. Children learn cultural values and problem-solving strategies by listening to their mother reading folk tales or to their father and other male adults exchanging stories, but also through observation of adults' attitudes, feelings, and behavioral responses to specific events. Through adult didactic instructions or nonverbal reactions, children learn

what is permissible action and emotional expression and what is not, and later infer that there are group norms governing such actions and emotional expressions. From an early age, in addition to these intersubjective experiences, culture is experienced by the child through exposure to various types of media, schooling, and socialization avenues.

Cultural knowledge and practice are not uniformly distributed among members of an ethnic group. Because members of an ethnic group share common values, beliefs, and practices, it used to be assumed that these were uniformly distributed across members. Weisner (2000, p. 141) has disputed this assumption of cultural uniformity, stating that "cultures may have a clear central tendency and normative pattern but they are hardly monolithic and uniform." Within an ethnic group, there are usually subgroups based at least on geography and social class. Within these various subgroups, there may be differential transmission, translation, and implementation of core values and beliefs. Even among members of the same subgroup, there are individual differences in the extent to which they have absorbed cultural values, beliefs, and practices. These individual differences are the result of several factors, including individual characteristics, differential socialization experiences, and differences among their parents' interpretations or implementations of cultural prescriptions. To paraphrase Kluckhohn and Murray (1953), a member of an ethnic group may be like all members of that group, like some members, and like no other members. Cultural uniformity cannot be taken for granted. Cultural knowledge and adherence among members of an ethnic group is characterized by diversity amid unity.

Culture as an Explanatory Variable

Before elucidating the significance of culture for development and psychopathology, a discussion of the controversy regarding culture as an explanatory variable seems warranted. The concept of culture is most often used simply as a descriptive variable, that is, as a category, index, or marker that serves to describe and distinguish values, beliefs, attitudes, and norms of one ethnic group from another. But the concept has also served as a dependent variable and also as an independent variable. It is a dependent variable, for example, in a study of the effects of schooling on women's definitions of gender roles, whereas it has the status of an independent variable in quasi-experimental studies that, for example, examine women's responsiveness to schooling as a function of their ethnic group's gender role definitions. It is culture's research function as an independent or explanatory variable that has encoun-

tered resistance (Garcia-Coll, Ackerman, & Cicchetti, 2000) and generated controversy.

Behavioral and social scientists are not always comfortable with the use of culture, however it is operationalized, as a causal explanation. Some would prefer to treat culture only as a descriptive variable or a dependent variable. Others who hold similar views think that, at best, culture may be conceptualized as a “tool kit” from which strategies for action can be selectively drawn for specific purposes (Patterson, 2000). There are several reasons for the unease that is evoked by cultural explanations. First, to those who construe culture as a distinctive product of a particular group of people, culture can be described and interpreted, but it should never be used to explain anything about the people who produced it because such explanations cannot be considered objective (Patterson, 2000). Second, scientists who are willing to consider culture as an explanatory variable are confronted by daunting conceptual and methodological issues. It is difficult to define culture, conceptually and operationally, even when it is disaggregated into its various components. Even when precise definitions are possible, cultural variables operate in a highly complex context, often interacting with a host of other influential variables such that it is difficult to isolate its effects. Furthermore, it is difficult to measure and quantify cultural variables. Psychometrically sound measures for many cultural variables do not yet exist. Moreover, prior attempts to identify cultural bases for behavior or social problems have yielded explanations that too often seem tautological, reductionistic, or static (Patterson, 2000). Third, there are cultural sensitivities to be considered. A search for the cultural bases of maladaptive behaviors can be construed as “blaming the victim” and might preclude changes in social policies and programs that can ameliorate those behaviors. Cultural explanations for maladaptive behavior might also offend ethnic pride. For these and other similar reasons, some scientists think that the safest approach is to describe culture or consider it as a dependent variable.

There is some truth to all of these arguments against treating culture as an explanatory variable. However, the conceptual and methodological problems noted are not unique to the study of culture. Definitional problems are not uncommon in the behavioral and social sciences, especially where relatively few empirical studies on the topic have been conducted. However, as progress is made in disaggregating culture into its various components and isolating it from confounding variables such as economic status, the task of defining and operationalizing cultural variables should become easier. Similarly, measurement and quan-

tification issues have been encountered in other areas and gradually resolved satisfactorily. Furthermore, the issue of complexity is a matter of conceptual clarification and methodological rigor. When there is some understanding of the different causal variables involved, adequate controls can be instituted to permit the isolation of the cultural variable from other variables or to at least examine the extent of its impact on the dependent variable as compared to other contributing factors. Identifying and disentangling the complex explanatory interplay between cultural and noncultural factors can be a stimulating research challenge. Granted that methodological improvements alone may not suffice to gain greater acceptance for the study of culture and its integration into mainstream psychology (Schweder, 1990, as cited in M. Cole, 1996), they are essential if we are to advance significantly in understanding the role of culture in human development and psychopathology.

In answer to those concerned with the possibility that if culture is found to have an effect, it will be concluded, erroneously, that culture determines a particular behavior, Goodenough (1989, p. 218) has made this rejoinder: “Biology helps explain human behavior but does not determine it. Similarly, culture helps explain behavior but it does not determine it either.” Finally, cultural sensitivity on the part of researchers can help to overcome an ethnic group’s concerns about research on its culture. Concerns about blaming the victim can be allayed by careful interpretation of the results and by using the research findings to advocate for policies and programs directed toward amelioration of any related maladaptive behaviors. A balanced program of research on culturally based values and practices that promote adaptive behaviors as well as maladaptive ones can identify ethnic group strengths that would be a source of ethnic pride.

In sum, the issues surrounding the use of culture as an explanatory variable can be resolved. Culture is so pervasive that not to explore its role as an explanatory variable is to ignore a potentially important source of variance in human behavior.

The Significance of Culture

If culture matters, how does it matter in regard to psychopathology? Culture’s relevance to understanding psychopathology derives from two distinguishable but interrelated roles: first, its role in human development, normal or otherwise, and second, its role in shaping societal perspectives on psychopathology and its nature, causes, course, diagnosis, assessment, treatment, and prevention.

Culture and Development

The role of culture in normal development has been discussed at length by developmental scientists (M. Cole, 1996; Garcia-Coll et al., 2000). Even before a child is born, culture defines how the developing fetus is to be treated in utero and at birth, and such treatment has implications for the child's subsequent health and development. Culture designates who will serve as the primary caregiver and how other kin and group members will contribute to the child's care. It also prescribes the appropriate caregiving contexts for infants, children, and adolescents. Most important, culture establishes socialization aims, emphasizing those that are most consistent with cultural values. The child-rearing practices employed to achieve socially desired developmental outcomes are also linked to cultural values, attitudes, beliefs, and norms. These practices may facilitate or inhibit the development of cognitive, emotional, social, and other processes that have implications for the emergence of psychopathology and for the prognosis of a disorder. There is growing evidence that the emergence of specific forms of psychopathology is associated with disruptions in the normal development of certain processes. These disruptions may be largely biologically based in some instances (e.g., Autism); in other cases (e.g., depression), they may be primarily the result of the interaction between biological factors and contextual factors, including specific cultural variables. And in still other cases, culture may be the primary contributing factor. Culture also structures the risk and protective factors that promote or prevent the development of psychopathology.

Culture and Psychopathology

Just as culture defines what is considered normal behavior in a society, so does it specify what is construed as deviant behavior. It categorizes and labels what is considered problem behavior or psychological dysfunction. Through its influence on how the environment is structured, culture helps to determine which behaviors are adaptive and mentally healthy and which are not. Psychopathology may have its intraindividual origins, but how it is experienced, labeled, and expressed is subject to cultural influences. There are even idioms of distress and prototypical behavioral patterns that are unique to societies, cultures, and subcultures. Both culturally distinctive symptoms and culture-specific syndromes have been identified. Culture offers its own culturally congruent explanations for deviant behaviors and psychological disorders. The role of culture and its interaction with biological factors in defining abnormal behavior is evidenced in a case that Greenfield (2002) used to

illustrate how culture and biology are mutually adapted for survival. In this case, the daughter of an American couple, social scientists living among the Zinacantec Maya of Nabenchauk in Chiapas, Mexico, began to walk at 9 months, about 5 months earlier than Zinacantec norms. For the Zinacantec, walking at 9 months of age was not only abnormal, it was also dangerous to walk before understanding language. This danger arose from the fact that the Zinacantec houses always have an open fire in the center. Because of this, the Zinacantec assumed that walking at 9 months placed the American child at risk for falling into the fire and her parents now needed to be in a constant state of high alert and close proximity to the child to prevent her from either getting hurt or causing some kind of damage. This case highlights the point that psychopathology has a culturally constituted definition and is referenced usually by the norms of the host culture that frame symptomatology, impairment of functioning, danger to self or others, and so on within the context of the local culture. What is viewed by the Zinacantec as abnormal behavior (making the American girl a *monster* in their eyes) is viewed as normal or even *precocious* in her American parents' eyes. In multicultural contexts, both the host (local) and non-host (foreign) cultures must be considered in defining the nature, causes, course, diagnosis, assessment, treatment, and prevention of *psychopathology*.

Culture's role extends beyond the description and explanation of psychopathology. It influences the course of the disorder and its prognosis because it structures environmental responses to behavioral distress and problematic behavior. Culture specifies the degree of behavioral intensity or problem severity that must be present before an intervention is necessary. Culturally based mental health beliefs and attitudes determine help-seeking responses. Culture designates who may intervene. Last, culture organizes the modes of intervention.

Given the potential significance of culture, a developmental-contextual approach to psychopathology has to address certain questions:

1. Do cultures vary in the expression of psychopathology? Are some patterns of symptomatology or mental disorders more prevalent in certain cultures than in others?
2. What aspects of a given culture are related to high or low prevalence of specific disorders? How do these cultural variables exert their influence? Is the influence direct or indirect? If the latter, what are the mediating variables?
3. What aspects of a given culture moderate the influence of risk or protective factors? How?

4. What is the role of culture in the development of those processes (e.g., emotional self-regulation) that have been implicated in the development of specific disorders (e.g., anxiety or depression)?
5. What are the mental health beliefs and attitudes of a given culture? How do these beliefs and attitudes structure help seeking, diagnosis, treatment, and prevention?

In sum, culture's significance in the study of developmental psychopathology derives from its role in normal development and development gone awry, as well as its role in shaping societal attitudes, beliefs, and practices pertaining to diagnosis, assessment, treatment, and prevention of psychopathology. These two conceptualizations of culture's role bear some resemblance to the two models of cultural influence proposed by Weisz, McCarty, Eastman, Chaiyasit, and Suwanlert (1997), but there are some subtle differences, at least in scope. As currently conceptualized, the two roles may be broader than those of the problem suppression-facilitation model and the adult distress threshold model proposed by Weisz et al.

In the next sections, we examine the available research literature bearing on culture's dual roles, with emphasis on studies of children and adolescents from diverse cultures. It is hoped that this review of development and psychopathology in diverse cultures will broaden our understanding of the role of culture in normal and deviant development. Currently, this understanding is based mostly on theories and research that describe normal and deviant development of European and European American children from middle and lower socioeconomic classes. In these studies, many explanatory variables (e.g., parental beliefs and expectations, child-rearing practices, communication strategies) are actually cultural variables even though they are not identified as such. It is not the case that the study of culture's role in human development and psychopathology has been neglected, but rather that the role of culture has been studied yet not acknowledged.

CULTURAL DIVERSITY IN CHILD AND ADOLESCENT PSYCHOPATHOLOGY

The assumption that culture influences the development, diagnosis, assessment, and treatment of psychopathology is a long-standing one, but to date, the research literature on culture and psychopathology during infancy, childhood, and adolescence is sparse and fragmented. Most of the available data are derived from comparative studies. Al-

though the number of ethnic or cultural studies on adult psychopathology is rapidly increasing, this does not apply to child psychopathology. Developmental-contextual studies that attempt to examine the relationship between culture and psychopathology among children and adolescents are just emerging. Longitudinal studies are even rarer. Our review includes findings from both types of studies.

In the research literature, two terms are used in referring to research involving more than one ethnic group. The term "cross-cultural" is usually used to denote between-group research using samples from two or more countries or nations; the term "ethnic" is applied to between-group research involving different ethnic groups residing within the same country or nation. This seems an artificial distinction, for in both cases, the intent is to discover if there are culturally based differences in the phenomenon under investigation. However, to avoid creating further confusion, we follow this convention for designating research between ethnic groups.

CULTURAL VARIATION IN EXPRESSIONS OF PSYCHOPATHOLOGY

We begin our examination of the relationship between culture and psychopathology by asking the question, Are there cross-cultural or ethnic differences in the expression of distress or psychopathology? Such differences would denote cultural diversity in psychopathology. It is acknowledged that cultural variations in psychopathology may be found in affective, behavioral, or linguistic expressions of distress or in the content of disturbed cognitions and sensory experiences (American Psychiatric Association, 2000), but the study of these variations in children and adolescents and how they change with increasing age has been ignored. Systematic studies directed at identifying, classifying, and validating such variations among children or adolescents are exceedingly rare.

Expressions of Symptomatology

Some interest has been shown in cultural variations in the symptomatology of anxiety. Cross-cultural research has shown that anxiety and disorders of anxiety are universal, or at least evident in all human societies where their presence has been assessed, but there are cultural variations in the phenomenology, meaning, and forms through which distress is expressed and constituted as social reality (Good & Kleinman, 1985). For example, Asians and Latinos may be more likely than European Americans to express anxiety

through somatic and/or physiological complaints. This ethnic difference has been investigated in a number of studies involving college students or older adults but rarely among children or adolescents. The hypothesis that Hispanic children and adolescents are more likely than their European American peers to express anxiety through somatic and physiological complaints has been confirmed in some studies, albeit with qualifications (Pina & Silverman, 2004; Varela et al., 2004). The manifestation of ethnic or cultural differences in somatic or physiological expressions of anxiety was a function of the measure used (Pina & Silverman, 2004). Moreover, although non-Cuban Latino youth showed greater distress over anxiety-related symptoms than their European American and Cuban Hispanic peers, within the non-Cuban Latino group, those whose parents preferred Spanish as the assessment language evidenced greater distress over anxiety-related symptoms than their peers whose parents chose English (Pina & Silverman, 2004).

Linguistic Expressions

The finding that the language in which assessment is conducted is associated with within-ethnic-group differences in somatic or physiological expression of anxiety and the amount of distress shown over anxiety-related symptoms highlights the role of language in the expression of distress. Besides serving as a means of communication, language serves as a stimulus in that it evokes cognitions and verbal and behavioral responses with associated emotions and other internal states. For bilingual and multilingual individuals, an assessment conducted in the first language may be more effective at tapping earlier modes of conceptualizing and expressing distress, regardless of acculturation status. Language may facilitate certain modes of symptom expression and inhibit others, depending on the affect and experiences that became associated with these modes in the individual's past. For example, acculturated immigrant adolescent girls might swear or discuss sexual matters with ease in English, but may be unable to do so or at least are more uncomfortable doing so in their native language. Moreover, there are cultural variations not only in the lexicon of emotion but also in the elaborateness of the language available for describing certain emotions and emotional experiences (Manson, 1996).

Behavioral Expressions

Few studies of Conduct Disorder or substance use have explored cultural variations in the expression of these prob-

lems or the differential cultural bases of apparently similar forms of expression. A couple of sociological studies illustrate such variations and show how the expression of antisocial tendencies may be patterned after existing cultural practices. In a study of Asian American youth gangs, Chin (1990a, 1990b, as cited in Chin, Kelly, & Fagan, 1992) identified four types of gang victimization in the Chinese American community that could be construed as involving business intimidation: protection, extortion, forced sales, and "theft" of goods and services. Although these types of business intimidation may also be used by gangs in other ethnic groups, an ethnographic study by Chin et al. (1992) shows how the expression of antisocial tendencies may be patterned after existing cultural practices. In this study, 603 merchants were interviewed to identify patterns of extortion and other forms of victimization practiced on Chinese-owned businesses by Asian adolescent gangs of predominantly Chinese descent operating in three Chinese neighborhoods in New York City. These interviews yielded data about the prevalence of these different types of gang victimization, when they occurred, and the behavioral patterns involved. The last is of particular interest here.

In the Chinese community, protection money, also known as *po foo fay* (protection fee), *tor ti fay* (territory fee), or *heung yau chin* (incense oil money), is money paid by merchants to an individual, gang, or association that controls the area where the business is conducted. As practiced by Asian American adolescents in New York City, asking for protection money is patterned after the Chinese tradition of asking for blessings on a new endeavor. The custom has been adapted to become a way to obtain the "blessing" of those (i.e., gangs) who are in a position to disrupt commercial activities or damage business properties. It is usually initiated at the opening ceremony launching a business, when some gang members accost the owner and present their proposal.

Extortion money is also known as *cha chin* (tea money), *hung bao* (red envelope), and *lai si* (lucky money, literally "good for business"). The various names signify several typical Chinese patterns of gift giving on specific occasions (e.g., giving a red envelope containing money to family members, relatives, and even strangers during the Chinese New Year) that have been subverted into forms of extortion. The practice of asking for extortion money is a sporadic, spontaneous act committed by young gang members on an irregular basis, mostly on major holidays such as the Chinese New Year.

Forced sales or the practice of selling items to business owners at prices higher than their market value, usually

during Chinese and other holidays, was the most pervasive type of gang exploitation uncovered by Chin et al. (1992). The items sold are typically associated with holidays such as firecrackers or cards or, during the Chinese New Year, mooncakes during the Moon Festival, and Christmas cards or whiskey during the Christmas holidays. To emphasize the “cultural connection,” teenage gang members sometimes add embellishments. For example, during one Chinese New Year, a teenage gang presented a merchant with a New Year card and asked him to pay \$180, adding that he would prosper during the entire coming year because the first digit denotes “one whole year” and the second digit is pronounced the same as the word “prosperity” in Cantonese.

“Theft” of goods and services involves the practice of gang members refusing to pay for or asking for heavy discounts on goods and services. In the Chinese community, this practice is called *saik pa wong fun* (eating the king’s meal) or *tai pa wong hey* (watching the king’s movie), with the perpetrator as the king who cannot be refused. This is essentially a power play, with the perpetrator’s material gain only secondary to the symbolic meaning it conveys. However, by construing the interaction between the offender and the victim in the traditional Chinese practice of “reciprocal face-giving behavior,” the interaction is normalized. The targets of this practice are usually owners of restaurants, bakery shops, barber shops, video rental stores, and other small retail businesses such as groceries and optical stores.

Young gang members who have grown up learning the traditional uses of these Chinese customs are introduced to their new functions in business intimidation by older gang members, including adults who themselves have adopted these practices from Hong Kong and Taiwan. The new applications of these traditional Chinese customs are taught through a combination of didactic instruction and modeling. Adherence is maintained through reinforcement and sanctions. Such socialization contrasts with what Moore and Vigil (1989) have reported about Chicano gangs. These investigators have argued that Chicano gangs do not promote crime but help with normal adolescent concerns around security, respect, and peer approval. In addition, they offer gender role identification and support, frequently providing street-culture role models when none are available at home, and helping the youth in managing identity conflicts (Vigil, 1988). These gang functions might also be true of other Asian American gangs and even of the one studied by Chin et al. (1992) but in the latter, tutoring in the subversion of cultural practices for ends that may be considered criminal also occurs.

Youth gangs from ethnic groups other than Asian American may also engage in the practice of business intimidation and in the specific types of gang victimization found by Chin et al. (1992). However, their modus operandi may differ from that of Asian American youth. The results of the Chin et al. study suggests that an exploration of what lies behind surface similarities in antisocial behavior will reveal culture-specific origins that are of interest to researchers seeking to understand how culture influences the expression of psychopathology. Such cultural variations may not greatly affect diagnosis or prevalence rates based on a particular nosology, but they may have implications for intervention.

CULTURAL DIVERSITY IN PREVALENCE RATES

A review of research on cross-cultural or ethnic differences in psychopathology is an appropriate starting point for examining the role of culture in psychopathology. Although any obtained cross-cultural or ethnic differences may be related to factors other than culture (e.g., socioeconomic status, a country’s level of economic development), their presence at least suggests that further investigation might reveal biologically based predispositions associated with race or cultural influences among the etiological factors. Cross-cultural or ethnic differences might be manifest in symptom features or patterns of symptom organization; differences in prevalence rates for specific disorders may be due to culturally related differences in definitions of problem behavior, help-seeking patterns, child-rearing practices, or risk and protective factors. Evidence for both types of manifestation are reviewed next.

Cross-Cultural Differences in Prevalence Rates

Prevalence refers to presence or absence of a symptom or a disorder in a population. Prevalence rate or estimate denotes the proportion of individuals in a population who manifest a particular symptom, symptom cluster, or disorder at a given point in time (Verhulst & Koot, 1992). Differences in prevalence rates of a particular symptom or disorder in two or more population groups may reflect underlying differences between these groups. One of those differences could be an aspect of culture. For example, cross-cultural differences in prevalence rates in a particular symptom or behavior might reflect culturally-based attitudes or modes of responding toward it. The assessment of

prevalence rates is a commonly used approach in cross-cultural research on psychopathology. Findings from recent research are reviewed.

Symptomatology

In one of the early cross-cultural studies on psychological problems, M. C. Lambert, Weisz, and Knight (1989) found differences between American and Jamaican reports of children's behaviors reflecting overcontrol versus undercontrol. Problems relating to overcontrol were reported significantly more often for Jamaican youngsters, a finding that was interpreted as consistent with Afro-British Jamaican cultural attitudes and practices that discourage child aggression and other uncontrolled behavior and that foster inhibition and other overcontrolled behavior. The classification of children's behaviors as overcontrolled or undercontrolled has proven to be a useful organizing principle in programmatic cross-cultural research on children's psychological problems for Weisz and his collaborators (M. C. Lambert et al., 1992; Weisz & Sigman, 1993; Weisz et al., 1997).

Achenbach and Edelbrock (1981) also conceptualized children's problems around the issue of behavioral control, specifically as externalizing or internalizing behaviors. The largest number of recent cross-cultural studies on this topic have employed the Child Behavior Checklist (CBCL; Achenbach, 1991a, 1991b) and Youth Self-Report (YSR; Achenbach, 1991c) or translations of these measures. Most studies compared children from two cultures. From a review of published studies, Verhulst and Achenbach (1995) concluded that although some significant differences in problem scores did emerge from studies comparing two cultures, there was a relatively small range of scores derived from administering the CBCL in 11 cultures and its other versions, the Teacher Report Form (TRF; Achenbach & Edelbrock, 1986) in 6 cultures, and the YSR in 3 cultures. Furthermore, there were no significant cross-cultural differences in cross-informant correlations between CBCL, TRF, and YSR scores.

To extend the analyses beyond comparisons of two cultures and achieve a broader, integrated view of children's externalizing and internalizing problems across a greater number of cultures, Crijnen, Achenbach, and Verhulst (1997) conducted an analysis using "omnicultural composites" (Ellis & Kimmel, 1992) derived from CBCL, TRF, and YSR scores collected in the Commonwealth of Puerto Rico and 11 countries (Australia, Belgium, China, Germany, Greece, Israel, Jamaica, the Netherlands, Sweden, Thailand, and the United States). This analysis permitted a test of cross-cultural variations in Total Problem, External-

izing, and Internalizing scores. The results showed significant effects for culture and gender on Total Problem scores from the 12 cultures. Age or interaction effects were not significant. Scores of participants from Puerto Rico, Greece, and China were significantly above the omnicultural mean, whereas those of their peers from Sweden, Israel, Germany, Australia, the Netherlands, and Belgium were significantly below. Boys had higher scores than girls. Culture, but not gender, was also found to have an effect on Total Problem scores of adolescents from 9 cultures. Puerto Rican adolescents had the highest score, and their Swedish counterparts had the lowest. Culture, gender, and age had significant effects on both Externalizing and Internalizing scores, but interactions did not reach significance. For both types of problems, Greek and Puerto Rican participants had scores significantly above the omnicultural mean compared to their Swedish, Dutch, Australian, and Israeli peers, whose scores fell significantly below. Further analyses comparing Externalizing and Internalizing problems revealed small but significant cross-cultural variations, although this finding is qualified because of significant interactions between culture and gender in the analysis of scores from 12 cultures and between culture, gender, and age in the analysis of scores from 9 cultures. Age and gender variations showed cross-cultural consistency. With increasing age, Total Problem and Externalizing scores decreased, whereas Internalizing scores increased; boys had higher Total Problem and Externalizing scores but lower Internalizing scores than girls. Finally, cross-cultural correlations were high among mean item scores. Crijnen et al. are inclined to attribute the cross-cultural variations found to methodological issues, but they do acknowledge that some cultural differences in the relationship between Externalizing and Internalizing scores, as revealed by interactions between culture and age, might possibly reflect differences in how cultures deal with Externalizing problem behavior.

They also note that despite variations among the 12 cultures in the distinctions they make between masculine and feminine roles (Hofstede, 1994), there were consistent gender differences in parent-reported Externalizing and Internalizing problems. Crijnen et al. (1997) hypothesize that this gender difference might represent a "cultural universal" (Berry et al., 1982, cited in Crijnen, 1997).

Cross-cultural comparisons of CBCL factor structure have yielded either similarities (deGroot, Koot, & Verhulst, 1994) or mixed results (Hartman et al., 1999). However, more cross-cultural differences than similarities were found in a study that compared clinic-referred children from two cultures (American and Thai) differing along multiple di-

mensions and that used parallel measures valid for each culture, the CBCL and Thai Youth Checklist (Weisz et al., 1987). In this study, a few syndromes (e.g., somatic problems) showed concordance across cultures, but more did not. Cross-cultural differences have been reported for both broadband and narrowband syndromes (Weisz, Weiss, Suwanlert, & Chaiyasit, 2003).

Apart from research examining the externalizing-internalizing dimension, recent cross-cultural studies of symptomatology in children and adolescents have focused on symptoms denoting anxiety. Cross-cultural studies of anxiety in children have largely been driven by attempts to establish the cross-cultural validity of certain measures. In general, the results of these studies show that certain developmentally linked fears, such as a fear of loud noises or of being separated from the primary caregiver, occur in children from many cultures and at about the same age. Furthermore, the pattern and content of fears in children from different cultures vary as a function of gender. English or translated versions of the 80-item Fear Survey Schedule for Children-Revised (FSSC-R; Ollendick, 1983a, 1983b) have been administered to children in several countries. These include, besides the United States, Australia, China, Italy, the Netherlands, Northern Ireland, Portugal, Turkey, and the United Kingdom. In a review of these studies, Fonseca, Yule, and Erol (1994) found generally comparable results across countries, except for the score on Total Fear. Scores on Total Fear were lower for the Dutch sample and higher for the Portuguese sample. The observed difference in Total Fear scores between Dutch and Portuguese children has been interpreted as possibly reflecting Nordic and Latin cultural differences in emotional expression and control. Caution about this interpretation is warranted, though, because a gradation of Total Fear scores along the Nordic-Latin dimension was not observed among the various samples. Gender differences were also observed across countries. A content analysis showed both commonality and diversity in children's fears. Among American, Australian, British, Portuguese, and Turkish children, the most frequently endorsed fear was being hit by a car. For children from at least four of those countries, fears of not being able to breathe, a bomb attack or war, fire, a burglar, falling from a height, and death were among the top 10 fears. In at least three countries (Portugal, Turkey, United Kingdom), several items appended to the original 80-item FSSC-R revealed that many children reported fear of a parent's death, with endorsements ranging from 73% to 84%.

There are also ongoing attempts to validate the State Trait Anxiety Inventory for Children (STAIC; Spielberger,

Diaz-Guerrero, & Strelan, 1990). One study (Ahlawat, 1986) yielded similar factor structures between the original STAIC and an Arabic version. Test anxiety has also been examined cross-culturally, using the Test Anxiety Scale for Children (Sarason, Davidson, Lightfall, Waite, & Ruebush, 1960). In a sample comparing children from Chile and the United States, the Chilean students scored higher on test anxiety than the American students (Guida & Ludlow, 1989). Cross-cultural studies of depressive symptomatology in children and adolescents involving countries other than the United States and those in Europe are rare.

Categorical Diagnoses

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM-IV-TR*; American Psychiatric Association, 2000), considers the possibility that some mental disorders are culture-bound or specific to certain cultures. Examples of these are *Ataque de Nervios*, *Susto*, and *Mal Puesto* among Hispanics, *Hwa-Byung* among Koreans, *Taijin Kyofusho* among Japanese, *Koro* among Chinese, and *Voodoo death* among those of African descent. These culture-bound syndromes have been identified in adults. A review of their occurrence in children and adolescents is not possible because relatively little is known of their manifestations in these age groups. Instead, our review concentrates on the prevalence of those disorders for which cross-cultural data from child and/or adolescent samples are available.

A primary goal of many cross-cultural studies that have assessed prevalence rates for different mental disorders is to establish the universality of a disorder or at least to determine if a specific disorder can be identified in two or more countries using the same diagnostic criteria. Cross-cultural research on Autism falls into this category. After reviewing epidemiological studies conducted in several countries, including Canada, England, Iceland, Japan, and Sweden, and brief reports from some countries in Eastern Europe, Klinger, Dawson, and Renner (2003, p. 429) concluded that there is "remarkable consistency in reports of autistic symptomatology, intellectual abilities, and gender differences, and socioeconomic factors associated with autism."

Attention-Deficit/Hyperactivity Disorder (ADHD) is another disorder that has been identified in different countries (Barkley, 2003), albeit with varying prevalence rates. These prevalence rates range from as low as 2% in Japan (Kanbayashi, Nakata, Fujii, Kita, & Wada, 1994) to 20% for boys in Italy (O'Leary, Vivian, & Nisi, 1985), and even as high as 29% for boys in India (Bhata, Nigam, Bohra, & Malik, 1991). These differences in prevalence rates might be a function of differences in diagnostic criteria, sample

characteristics, or measures, but such wide variations also raise the question of whether these cross-cultural variations in ADHD prevalence rates reflect differing cultural attitudes and responses toward the behavioral indices of the disorder. Bird (2002) makes the same points in a recent review of epidemiological studies carried out in different cultural settings around the world, including North America (United States, Canada), Great Britain and several other countries in Western Europe, the Asia/Pacific Rim (China, India, Japan, New Zealand), Brazil in South America, and Puerto Rico in the Caribbean. There was remarkable similarity in the pattern of behaviors characteristic of the syndrome, but prevalence rates varied, ranging from as low as 1% to as high as 20%. Bird is more inclined to attribute these variations in rate to differences in the diagnostic system used, methods of ascertainment, and other methodological artifacts rather than culture. He concluded that although ADHD is conceptualized in similar ways in different cultures, differences in rates occur because of an informant effect produced by culturally based differences in the threshold deviance, among both clinicians and other informants. Although Bird does not think so, the differences in the diagnostic system used and the methods of ascertainment may themselves be illustrative of cultural differences.

Anxiety Disorders have also been examined recently in several countries. In community samples, prevalence rates for Obsessive-Compulsive Disorder (OCD) range from 3% for clinical OCD (Valleni-Basile et al., 1994), 4% in community samples of adolescents in Italy (Maggini, Ampollini, Garibaldi, Cella, Peqlizza, & Marchesi, 2001) and older adolescents in Israel (Zohar et al., 1992), and 19% for subclinical OCD (Valleni-Basile et al., 1994). Rates for Simple/Specific Phobia include a lifetime prevalence of 3.5% among adolescents in Germany (Essau, Conradt, & Petermann, 2000) to a 6-month prevalence rate of 9.2% in Dutch adolescents (Verhulst, van der Ende, Ferdinand, & Kasius, 1997). The Dutch sample also yielded a higher rate (6.3%) of Social Phobia than the 1.1% found in a New Zealand sample (McGee, Feehan, Williams, & Partridge, 1990). In addition, a lifetime prevalence rate of 1% for Panic Disorder was found among the Dutch adolescents (Verhulst et al., 1997).

The paucity of cross-cultural research on depressive symptomatology is also true for research on mood disorders in children and adolescents, despite the fact that both have been studied extensively in adults from a cross-cultural perspective. In this respect, cross-cultural research on childhood depression parallels that on childhood Schizophrenia.

Potentially, cross-cultural research has the most to offer for understanding the relationship between culture and psychopathology. The comparative studies reviewed here show that a conceptualization of problem behaviors along the externalizing-internalizing dimension can be employed usefully in different cultures. Furthermore, they reveal that certain mental disorders, notably Autism, ADHD, and Anxiety Disorders can be identified in several cultures, albeit with some variation in prevalence rates. In other words, they provide information about the occurrence and frequency of symptomatology or disorder. They also demonstrate the consistency of a gender difference in pattern and content of symptomatology. Whether this gender difference is culturally based has yet to be determined. Last, they indicate that certain categories of the *DSM* nosology (e.g., Autism) and certain measures developed for American samples (e.g., CBCL, FSSC-R) can be successfully used in other cultures. Beyond these, the findings do not offer much more toward elucidating cultural influences on psychopathology. One reason is that most of these studies were not designed to explore cultural influences but to test the cross-cultural generalizability of a particular conceptualization of psychopathology or to test the usefulness of a specific measure in other cultures. In addition, methodological variations in data collection from several cultures may be confounded with cross-cultural variations, thus making it difficult to arrive at any conclusions regarding cultural influences (e.g., Crijnen et al., 1997). This difficulty can be overcome in future cross-cultural studies through the use of similar sampling techniques and other data collection methods across sites. Another possible reason is that the studies reviewed employed an etic approach, applying concepts and measures derived from one culture to another culture presumably different from the first. The term, *etic*, refers to concepts and methodologies that are universal whereas the term, *emic* applies to those that are group-specific or culture-specific. Berry (1969) distinguished two types of etic: an *imposed etic* when universality is assumed and a *derived etic* when universality has been demonstrated by research. Often, the culturally based rationale for the cross-cultural comparison was not clearly articulated. Furthermore, except for a few studies that added items to the FSSC-R, little was done beyond translations to modify or add measures that might reveal cultural differences. To date, cross-cultural research on psychopathology may be characterized as a search for universals or, at least, for cross-cultural validity of nosology and measures.

Preliminary studies using an emic approach or the combined use of emic and etic approaches might prove more illuminating about the role of culture in psychopathology.

For example, because items on a measure may already represent one level of abstraction from a set of behaviors, different sets of behaviors may underlie an identical response from respondents in different cultures. This implies that direct observations, one-to-one interviews, and focused groups may be needed, along with standardized tests, to detect cultural influences. Moreover, where cross-cultural variations in patterns of symptomatology or prevalence rates did emerge, there were few efforts to examine possible cultural correlates or, at least, the cultural lens through which behavior was viewed that produced differences in rates. Obtained prevalence rates reflect the child's actual behavior and the lens through which it is viewed by others within the same culture (Weisz et al., 2003). In sum, this set of studies accomplished an important first step toward understanding the role of culture in psychopathology. Epidemiological studies and measurement construction are necessary, but not sufficient. Other, more critical steps have yet to be taken.

Ethnic Differences in Prevalence Rates

Empirical studies on ethnic differences in symptomatology and psychiatric disorders among American ethnic minority children and youth have increased in recent years, although still far fewer than the number of studies on European American children or even ethnic minority college students and older adults. The samples used in these studies are also larger in size, no longer limited to convenience samples, and even include probability samples. The available studies have been conducted mainly among the four major ethnic minority groups: African Americans, Asian Americans and Pacific Islanders, Hispanics or Latinos, and Native Americans. Before proceeding with this review of recent empirical studies involving these four ethnic minority groups, it should be mentioned that there are two other important potential sources of scientific data on cultural influences on adaptation, development, and psychopathology. One is the excellent programmatic research on psychopathology among Puerto Ricans residing in Puerto Rico (and therefore not considered an American ethnic minority group) conducted by Bird, Canino, and their colleagues (e.g., Canino et al., 2004). This review will not attempt a thorough coverage of their work but does review those studies that included Island Puerto Ricans in a study of mainland Puerto Ricans and other American ethnic minority groups. The other source is the emerging body of empirical studies on newly arrived immigrant and refugee ethnic groups from Eastern Europe and the former Soviet Union and from several African countries (e.g., Birman, 2005). Relatively

few of the latter have focused on prevalence rates for different kinds of symptomatology or categories of psychiatric disorders, so they will not be reviewed here. In the future, studies of these newly arrived ethnic groups will broaden our scientific database on cultural influences on development and psychopathology.

The preceding review of cross-cultural research on psychiatric symptomatology in children and adolescents suggests that in many cultures, psychological problems can be usefully organized along the externalizing-internalizing dimension, so our review of ethnic differences in psychopathology will be organized likewise. Also, for the sake of coherence, our review is limited to those few disorders that have received the most attention, resulting in a cluster of related studies: Conduct Disorder and substance use/abuse among the externalizing disorders and Anxiety Disorders and depression among the internalizing disorders. For each of these topics, the presentation begins with ethnic differences in symptomatology, followed by ethnic differences in disorders and, if available, data on comorbidity. Then data from noncomparative studies (i.e., studies that looked at only one ethnic minority group) that are consistent or inconsistent with the observed differences are discussed. Within-group differences are examined when pertinent data are available. Finally, the course or development of the disorder is described, again depending on the availability of data. Also for each topic, findings concerning African Americans are presented first, followed by those for American Indians, Asian Americans/Pacific Islanders, and Latinos.

Externalizing Problems and Disorders

Behavior can be conceptualized along a continuous dimension ranging from covert to overt, internal to external, or inhibition to action. Following this view of behavior, problem behaviors can be classified as externalizing or internalizing problems or syndromes. This dimensional approach to the classification of problem behaviors has received strong empirical support, most notably from research conducted by Achenbach and his collaborators (e.g., Achenbach & Edelbrock, 1981; Achenbach, Howell, Quay, & Conners, 1991). Externalizing problems refer to problem behaviors that involved acting out or under-controlled behavior such as aggression, anti-social behaviors, and opposition. Correspondingly, disorders characterized by symptoms that are externalizing problems are considered externalizing disorders. In this section, we chose to review two externalizing problems and disorders for whom prevalence rates from epidemiological studies are available: conduct problems and

disorders, as well as substance use and substance-related disorders. Because there are many studies of substance use and substance-related disorders, our review is limited to those that studied American Indians because these topics seem to have been investigated proportionately more than any other mental health-related topic in this population and the number of available studies allowed for a more comprehensive view of the problem and its progression.

Conduct Problems

According to Elliott, Huizinga, and Ageton (1985), minority status is associated with antisocial behavior in the United States, with elevated rates of antisocial behavior in African Americans, Latino Americans, and Native Americans. Conduct problems, particularly antisocial behaviors and substance use, of ethnic minority children and youth have received a great deal of attention from researchers. However, although many of the studies included large numbers of ethnic minority participants (e.g., African Americans), ethnicity was not included as a variable in the data analyses. Among those that were specifically interested in ethnic differences, several early studies employing community or clinical samples of children and/or adolescents have yielded some ethnic differences in symptomatology (e.g., Costello, 1989; Velez, Johnson, & Cohen, 1989). However, studies that controlled for sex, age, socioeconomic status (SES), or referral status, particularly those employing large national samples, revealed few or no ethnic differences in antisocial behavior among European, African, and Latino American children (Achenbach & Edelbrock, 1981; Achenbach, Howell, Quay, & Conners, 1991; Lahey et al., 1995).

Conduct Disorders

Data from the Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) study (Lahey et al., 1996; D. Shaffer et al., 1996) were used by Bird et al. (2001) to determine the prevalence of Conduct Disorder (CD), Oppositional Defiant Disorder (ODD), and various levels of antisocial behavior, as well as their correlates, in three ethnic groups: Latinos, subdivided into Island Puerto Ricans and Mainland Latinos, African Americans, and Mainland non-Latino, non-African Americans. All groups were representative samples of four geographically and ethnically diverse communities. The prevalence rate for CD was significantly lower in the Island Puerto Rican sample than in the African American sample. Significant differences in prevalence rates for ODD also emerged: The three ethnic groups on the mainland had higher rates than the Island Puerto Ricans. Bird et al. (2001) also examined the preva-

lence rates for five levels of antisocial behavior representing a hierarchy of seriousness/severity. Again, the three mainland ethnic groups showed higher rates than the Island Puerto Ricans, specifically for level 3 (e.g., lying, disobedience) and level 4 (e.g., damaging property, attacking someone). At first glance, these lower prevalence rates for CD, ODD, and levels of antisocial behaviors seem inconsistent with the Crijnen et al. (1997) finding that among children from 12 cultures, Island Puerto Ricans showed the highest prevalence rate for Externalizing scores. Methodological differences, particularly in sampling, measures, testing procedure, and translation, may largely account for the apparent inconsistency.

Substance Use

Surveys of large samples have yielded reliable information about substance use among American Indians. Plunkett and Mitchell (2000) compared reports on substance use obtained from American Indian high school seniors who participated in the Voices of Indian Teens study (1993, as cited in Plunkett & Mitchell, 2000) with those from non-Indian high school seniors who participated in the Monitoring the Future study (Johnston, O'Malley, & Bachman, 2000, 2001). They found that lifetime substance use among American Indian youth was significantly higher than that of non-American Indian youth for two substances, marijuana and cocaine, whereas non-American Indian youth had significantly higher lifetime use of inhalants and cigarettes. Furthermore, American Indian youth reported significantly higher 30-day use for five (marijuana, cocaine, stimulants, alcohol, and barbiturates) of seven substances assessed than did their non-American Indian peers.

Within-group differences in substance use among American Indians may exist. A study of psychological adjustment among American Indians (Gray & Winterowd, 2002) showed that American Indian students residing in a rural but nonreservation area reported average or below-average levels of health risks, including substance use. However, this study did not include a control group, so it merely suggests a hypothesis that has still to be verified in a study with a better research design. Within-group differences in substance use as a function of region have also been reported for American Indian youth. Plunkett and Mitchell (2000) performed a geographic analysis of their data on substance use from American Indian and non-American Indian teens. This analysis revealed regional variations in patterns of substance use: American Indian youth reported significantly higher rates of more lifetime substance use items in one region; in another region, it was non-American Indian youth who reported significantly higher lifetime

substance use. Controlling for region, American Indian youth rates were significantly higher on only three of the seven substances.

A more comprehensive picture of American Indian youth use of substances, with implications for developmental psychopathology, is provided by a study of trends in drug use among American Indian adolescents attending schools on or near Indian reservations in the United States (Beauvais, Jumper-Thurman, Helm, Plested, & Burnside, 2004). Using data from reliable and valid school-administered drug use surveys given every year for 25 years (1975–2000) to representative samples of Indian youth living on reservation and data from non-Indian youth participating in the Monitoring the Future study, Beauvais et al. compared the two groups on lifetime prevalence, use in the past 30 days, and proportions at high risk and at moderate risk and subjected the differences to proportion tests. They found that, in comparison to non-Indian youth, the reservation Indian youth had elevated levels of drug use for most illicit drugs from 1975 to 2000. However, the trends showing increases and decreases over time were similar for the two groups. A comparison of trends among those who engaged in moderate and high use showed that the number of youth in the moderate category varied over time, whereas the number in the high category remained relatively constant.

The sequence of substances used by American Indian adolescents has also been studied. Novins, Beals, and Mitchell (2001) reported that the predominant sequential pattern of use of different classes of substance among a large sample of American Indian adolescents is consistent with a stage theory that was proposed for other ethnic groups. According to this theory, adolescents start with alcohol, then use marijuana, then other illicit drugs, and progress to the use of cocaine. A survey of 1,562 high school students in 1993 (Novins et al., 2001) revealed that 35% of the participants who were using alcohol and marijuana reported using alcohol first, a sequence consistent with stage theory. However, 75% of youth who had used three or more substances reported a sequence of first use that was inconsistent with stage theory. Thus, although overall, a general pattern of using alcohol, marijuana, and/or inhalants prior to the use of cocaine and other illicit drugs emerged, it also appears that alcohol, marijuana, and inhalants are all initiating substances for American Indian youth. Variations in the sequences of first use were a function of gender, age of first substance use, community, and number of classes of substances use. In another study, Novins and Baron (2004) assessed the risk of substance use and progression of substance use in American Indian adolescents ages 14 to 20 years who participated in two or

more consecutive waves of a longitudinal study conducted between 1993 and 1996. They found that the risk for initiating use of any substance accelerated in early adolescence and peaked at age 18. The risk for progression from use of alcohol, marijuana, and/or inhalants to the use of other illicit drugs (e.g., cocaine) increased over the first 4.5 years after initiating substance use, then diminished in subsequent years. Adolescents who initiated substance use with marijuana or inhalants were more likely to progress to other illicit drugs than their peers who initiated substance use with alcohol. Novins and Baron also reported that the risk of substance use initiation and progression varied across the four participating communities and by the season of the year.

Substance-Related Disorders

Using the Diagnostic Interview Schedule for Children (DISC) Version 2.1C (Shaffer et al., 1988 as cited in Beals et al., 1997) and following criteria in the *Diagnostic and Statistical Manual*, third edition, revised (*DSM-III-R*; American Psychiatric Association, 1987), Beals et al. (1997) assessed the prevalence of psychiatric disorders among 109 American Indian adolescents, *M* age = 15.6 years, living in a Northern Plains community. Prevalence rates were reported based on the diagnosis-specific impairment criteria. The use of such criteria, they argue, is a step toward cultural validity because it places the symptoms in an environmental context and it more closely approximates the clinical diagnostic process in which the clinician incorporates multiple factors (including degree of impairment and culture) into the assessment. Twenty-nine percent (29.4%) of the sample received a diagnosis of at least one psychiatric disorder, 16.5% qualified for a single diagnosis, and 12.9% met criteria for comorbid disorders. Those diagnosed for substance use disorders made up the largest group (18.3%), followed by those diagnosed for one or more of the disruptive behavior disorders. Alcohol dependence/abuse, marijuana dependence/abuse, and substance dependence/abuse ranked among the five most common specific disorders. Comorbidity was not uncommon: More than half of those with a disruptive behavior disorder also qualified for a substance use disorder, and more than half of those with depressive disorders had a substance use disorder.

Beals et al. (1997) did not include a comparison sample in their study, but they compared their data with those obtained in previous studies (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993; Shaffer et al., 1996) whose participants represented other groups, including European Americans. When compared to the adolescents in the

MECA study (D. Shaffer et al., 1996), American Indian adolescents exhibited substance use/dependence disorders. Similarly, when compared to the adolescents studied by Lewinsohn et al., they demonstrated statistically significantly higher 6-month prevalence rates for lifetime prevalence of alcohol abuse/dependence disorder. In addition, the American Indian sample had a significantly higher rate of comorbidity between substance use disorders and disruptive behavior disorders.

Costello, Farmer, Angold, Burns, and Erkanli (1997) examined the 3-month prevalence of *DSM-III-R* psychiatric disorders, the social and family risk factors for these disorders, and met and unmet needs for mental health care in a representative sample of European American and American Indian children ages 9, 11, and 13 years living in southern Appalachia. They found that American Indian children had a slightly lower overall prevalence of psychiatric disorders than the European Americans, an ethnic difference that, according to the investigators, was largely accounted for by different rates of tic disorders in 9-year-old boys. They also reported an ethnic difference in substance use. Although substance use was low in both ethnic groups, at 13 years of age, significantly more American Indian than European American children reported recent use of alcohol. Furthermore, comorbidity of substance use and psychiatric disorder was higher in the American Indian sample. Comorbidity among American Indian youths (ages 13 to 18 years) identified as having a substance abuse disorder has also been reported by Fiskenscher and Novins (2003). They found that 74% of 89 American Indian adolescents receiving treatment for substance abuse also met full *DSM-IV* criteria for Conduct Disorder based on their responses to the Diagnostic Interview Schedule for Children, Youth Version, and the Composite International Diagnostic Interview. Conduct Disorder was common among both boys and girls in this sample of American Indian adolescents, but the specific antisocial behaviors displayed and the relationships to other psychiatric disorders varied by gender.

Despite the use of different methodologies, both the Beals et al. (1997) and the Costello et al. (1997) studies indicate that American Indian adolescents engage in higher rates of substance use and exhibit higher rates of psychiatric comorbidity. This ethnic difference is present at 13 years of age (Costello et al., 1997) and is also manifest in 15-year-olds (Beals et al., 1997). These findings from different samples suggest that once substance-related disorders emerge in early adolescence, they may persist and remain relatively stable in subsequent years. A prospective longitudinal study could verify this or reveal other devel-

opmental trends. Survey data on trends in drug use among American Indian youth show that there is a decrease in late adolescence and young adulthood, but this may not be the case for those whose substance use during early and/or middle adolescence is severe enough to meet the criteria for a *DSM-IV* substance-related disorder.

Internalizing Symptoms and Disorders

Internalizing problems are those problem behaviors that reflect internal distress that is not directly expressed in overt action but indirectly through social withdrawal, anxiety, somatic complaints, or depressed mood. Internalizing disorders are those disorders whose primary symptoms consist of internalizing problem behaviors including the different anxiety disorders, posttraumatic stress disorders, and mood disorders. Most studies of internalizing symptoms or disorders among ethnic minority children and adolescents deal with anxiety symptomatology or disorders and, to a lesser extent, with depressive symptomatology or unipolar depression.

Anxiety Symptoms

As was the case in cross-cultural research, symptoms denoting anxiety in ethnic minority children and youth have received a relatively large share of researchers' attention. Ethnic differences in fear or anxiety have been found in several studies, suggesting that ethnicity or a factor related to ethnic membership is associated with reported levels of fear or anxiety. In a study of a clinical sample, Last and Perrin (1993) found that African American children tended to score higher than their European American peers on the FSSC-R (Ollendick, 1983a, 1983b). Neal, Lilly, and Zakis (1993) also used the FSSC-R to assess the change and stability in the fears of African American children from primarily working-class and low-income families and their European American counterparts. Overall, the children's reported fears were relatively stable over a 2-week period, but African American children's fears were less stable than those of their European American peers. Follow-up assessments (Neal & Knisley, 1995) did not reveal ethnic differences in the rank order that children assigned to their fears; across ethnicity, sex, and grade, the top-ranked fears were those involving possible harm to self or others. Neal and Knisley did not report any ethnic differences in total mean FSSC-R scores across the three assessments. However, they did note that correlational analysis of FSSC-R scores over time showed a significant difference in the stability coeffi-

cients of African American and European American children from the original to the 12-month assessment. Over 12 months, African American children's total fear scores showed greater stability than European American children's. The stability of total fear scores also varied as a function of sex and time of reassessment. Boys' total fear scores were more stable than those of girls, but only from the original to the 5-month assessment. For boys, the mean total fear scores decreased after a 5-month interval from the first assessment but increased from the 5-month to the 12-month administration. For girls, the mean total fear scores decreased from the original to the 5-month administration but remained essentially the same from the 5-month to the 12-month assessment. Stability also varied as a function of grade. For younger children, the mean total fear score decreased from the original to the 5-month administration and increased from the 5-month to the 12-month assessment. For older children, mean total fear score decreased from the original to the 5-month assessment but remained relatively the same from the 5- to the 12-month administration.

Data on anxiety sensitivity in African American children come from a study by S. F. Lambert, Cooley, Campbell, Benoit, and Stansbury (2004) that examined the psychometric properties of the Children's Anxiety Sensitivity Index (CASI; Silverman, Fleisig, Rabian, & Peterson, 1991) in a sample of African American children in grades 4 and 5. Because the aim of the study was to assess the psychometric properties of the CASI, there was no comparison group, but results of prior studies provided some basis for comparison. The mean level of anxiety sensitivity among African American children in the S. F. Lambert, Cooley, et al. sample was higher than that found in European American children by Silverman et al. (1991) and among African American adolescents examined by Ginsburg and Drake (2002). However, anxiety level was comparable to that obtained by Rabian, Embry, and McIntyre (1999) in an ethnically diverse community sample (64% African American). Unlike in previous studies of African American adolescents (Ginsburg & Drake, 2002; White & Farrell, 2001), no sex differences were found by S. F. Lambert, Cooley, et al. The lack of sex differences may be due to differences in age, socialization, and/or context.

Some differences in anxiety symptomatology have been found between European American and Asian American children. Shore and Rapport (1998) examined the structure and developmental pattern of fearfulness in an ethnoculturally diverse sample of 385 children, ages 7 to 16 years, living in Hawaii. They reported a significant effect for eth-

nicity on FSSC-R scores. None of the interactions was significant. Between-group comparisons showed that European American children were less fearful than children from Asian (i.e., of East Asian descent, such as Chinese and Japanese Americans), Filipino, and Hawaiian backgrounds. They had significantly lower FSSC-R Total scores than Asian Americans, Filipino Americans, and Native Hawaiian children. Specific subscale scores also differed significantly among the ethnic groups. European Americans scored lower than Asian Americans, Filipino Americans, and Native Hawaiians on all seven subscales, but only some of these subscale ethnic differences were significant. European Americans' subscale scores on fears of danger, death, and animals differed significantly from those of Native Hawaiians and Asian Americans but not in comparison to those of Filipino Americans. European Americans also did not differ significantly from Native Hawaiians in Anticipatory Social Fears scores. Filipino Americans had significantly higher scores on Anticipatory Social Fears than all the other groups. Consistent with earlier findings, fearfulness, whether indexed by total scores or prevalence scores, was greater in girls than in boys. On both indices, younger children also demonstrated more fearfulness than older ones.

Some ethnic differences between European American children and adolescents and their Latino counterparts have also been reported. Using a Spanish translation of the Revised Children's Manifest Anxiety Scale (RCMAS; Reynolds & Richmond, 1978) deemed culturally sensitive, Varela et al. (2004) examined the reporting of anxiety symptoms among Mexican, Mexican American, and European American children ages 10 to 14 years ($M = 11.1$). As expected, Mexican and Mexican American children reported more physiological anxiety symptoms and more worry symptoms than European children. Mexican and Mexican American children did not differ in physiological symptoms or worry/sensitivity. A subsequent analysis that controlled for scores on the Lie scale, SES, and age of child yielded similar findings. Mexican children endorsed more items on the Lie scale of the RCMAS than did Mexican Americans and European Americans. The two American ethnic groups did not differ from one another on the Lie scale.

In one study, ethnic differences in anxiety symptomatology did not hold up after corrections for experiment wise error were applied. Pina and Silverman (2004) examined the clinical phenomenology, somatic symptoms, and perceptions of anxiety-related somatic/physiological symptoms as distressing among 6- to 17-year-old Latino and European American youth. Latino participants were either

of Cuban descent or not. All participants had been administered the Anxiety Disorders Interview Schedule for Children and, based on *DSM-IV* criteria, received a primary diagnosis of Anxiety Disorder. The types of Anxiety Disorder differed; the most common was Separation Anxiety Disorder (SAD), followed by Specific Phobia, Generalized Anxiety Disorder, Social Phobia, and Panic Disorder. Preliminary analyses comparing Latinos and European Americans failed to yield significant differences in scores on the FSSC-R and STAIC but showed a significant ethnic difference in scores on the RCMAS, which disappeared in a subsequent analysis that applied Holm's modified Bonferroni correction. When the Latino sample was further subdivided into Cuban American and non-Cuban American, then compared with European Americans, significant differences in STAIC-T scores emerged, but these, too, did not hold up after Holm's modified Bonferroni correction was applied.

Pina and Silverman (2004) did find ethnic differences in somatic symptoms. These investigators used CBCL somatic T scores and RCMAS Physiological scale scores as indices of somatic symptoms. European Americans and Cuban Americans had significantly lower CBCL somatic T scores than the non-Cuban Americans, a difference that remained even after applying Holm's method. This difference also emerged in a subsequent analysis that included the parents' choice of language (English or Spanish) for the assessment. No significant differences in RCMAS Physiological scale scores were found initially, but when the Latino parents' preferred language for the assessment was included in a subsequent analysis, among the Latino youth whose parents chose English, the non-Cubans had higher RCMAS Physiological scale scores, a difference that disappeared after applying Holm's modified Bonferroni correction. The results of this study suggest that the CBCL may be better than the RCMAS at detecting ethnic differences in somatic symptoms. Pina and Silverman also examined parental reports of somatic symptoms. Parents of European American and Cuban American youths reported their offspring as having fewer somatic symptoms than did parents of non-Cuban American youth.

The degree to which anxiety-related somatic/physiological symptoms are found distressing or aversive by Latino versus European American youths was also investigated by Pina and Silverman (2004). It has been suggested that in addition to expressing distress and worry as somatic/physiological symptoms, Latino youth might at the same time be distressed further by the presence of this symptomatology. For example, a child who is experiencing anxiety-related somatic symptoms might say, "My stomach hurts so much, I worry that I might be very sick." According to Pina and

Silverman, the distress evoked by somatic symptoms is akin to the construct of anxiety sensitivity (Reiss, 1997) in the anxiety research literature. In their study, distress over anxiety-related somatic signs was operationalized as Total scores and Disease Concerns scale scores from the Childhood Anxiety Sensitivity Index (CASI; Silverman et al., 1991). European Americans reported significantly lower CASI Total scores and CASI Disease Concerns scores than non-Cuban American youths. Furthermore, exploratory analyses that included Latino parents' language choice as a variable showed that Cuban American youths whose parents chose to have the assessment administered in English reported significantly less distress associated with anxiety-related somatic/physiological symptoms than non-Cuban American or Latino youth whose parents chose the assessment in English. Among the Latino youth whose parents preferred the assessment in Spanish, Cuban Americans reported significantly more distress than non-Cuban Americans. These findings remained statistically significant even after correction for experiment wise error was applied.

Pina and Silverman's (2004) findings that Latino and European American youths with anxiety disorders differ significantly in terms of somatic/physiological symptoms and distress over these symptoms are consistent with those found in a community sample of adolescents (Weems, Hayward, Killen, & Taylor, 2002) and adults (Novy, Stanley, Averill, & Daza, 2001). Furthermore, they show that among Latino youths, anxiety-related somatic/physiological symptoms and the degree of distress associated with these symptoms vary as a function of ethnocultural group and parents' choice of language for their assessment.

In addition to showing ethnic differences in total and subscale scores on measures of anxiety symptomatology, studies have also revealed some ethnic differences in the structure or patterns of organization of anxiety. Whereas previous research with European American children had shown that the FSSC-R has five factors (e.g., Ollendick, Yule, & Ollier, 1991), an exploratory factor analysis on the data collected by Neal et al. (1993) revealed that a three-factor solution provided the best fit for the data from African American children. The three factors were (1) fear of death, danger, and small animals; (2) fear of the unknown and things that crawl; and (3) medical fears. An ethnic difference in the factor structure of the FSSC-R was also reported by Shore and Rapport (1998). These investigators revised the FSSC-R to make it suitable for children residing in Hawaii, then examined the reliability, validity, and factor structure of the revision, the Fear Survey Schedule for Children-Hawaii (FSSC-HI), and compared it to the FSSC-R and FSSC-II. They found that a seven-factor solu-

tion provided the best conceptual fit for the data; six factors were similar to those identified in earlier versions of the FSSC, but the seventh was not. This unique factor reflected children's social conformity fears.

An ethnic difference in the factor structure of the CASI has also been reported. Exploratory analysis of CASI data from African American children has yielded a different factor structure than that obtained from European American children by Silverman et al. (1991). S. F. Lambert, Cooley, et al. (2004) found that for the CASI data from their sample of African Americans, two factors, Physical Concerns and Mental Incapacitation, provided the best fit in a conceptually meaningful way, whereas Silverman et al. reported that a hierarchical structure with three or four first-order factors (Physical Concerns, Mental Incapacitation Concerns, Control, Social Concerns) best fit their CASI data. More recently, Silverman and her colleagues (Silverman, Goodhart, Barrett, & Turner, 2003) reported that a confirmatory analysis of CASI data from across several studies yielded support for a hierarchical model with a single second-order factor and four lower-order factors (Disease Concerns, Unsteady Concerns, Mental Illness Concerns, Social Concerns). These ethnic differences in factor structures suggest that culture influences not only the expression of anxieties, concerns, fears, and worries but also their cognitive patterns of organization.

Anxiety Disorders

Ethnic differences in Anxiety Disorders have also been explored. The evidence on ethnic differences in Anxiety Disorders between African American children or adolescents and their European American peers is mixed. An ethnic difference was found in one study that included relatively large community and clinical samples, but other studies using clinical samples only have found no evidence or limited evidence. In a study that included community ($n = 2,384$) and clinical ($n = 217$) samples, Compton, Nelson, and March (2000) found ethnic differences in the patterning of Anxiety Disorders that were consistent across the two samples despite the large sample size difference. In the community sample, both preadolescent and adolescent African Americans endorsed more symptoms of SAD and fewer symptoms of Social Phobia than their European American peers on the Multidimensional Anxiety Scale for Children. European Americans reported lower Separation Anxiety and higher Social Phobia. Similar results were obtained from the clinical sample.

Last and Perrin (1993) examined *DSM-III-R* Anxiety Disorders in a clinical sample of African and European American children. They did not find any ethnic group dif-

ferences in age, sex, duration of disorder, or lifetime history of Mood Disorder. However, there was a trend for African American children to report a history of Posttraumatic Stress Disorder, whereas European American children showed a trend toward more frequent reports of school refusal and higher diagnostic severity ratings. The investigators raised the possibility that the trend's failure to reach an acceptable level of statistical significance might have been due to the African American sample ($n = 30$) being much smaller than the European American one ($n = 139$). Beidel, Turner, and Morris (1999, 2000) compared African American and European American children with Social Phobia with respect to clinical presentation and treatment outcome. They found only one significant ethnic difference: European American children had higher scores on the Social Phobia and Anxiety Inventory for Children (SPAIC; Beidel, Turner, & Morris, 1995). Ferrell, Beidel, and Turner (2004), however, failed to find ethnic differences in Social Phobia and related symptoms (depression, loneliness, neuroticism, and state-trait anxiety), social skills, or social anxiety in a sample of 39 European American and 19 African American children referred for treatment of Social Phobia. With respect to diagnostic criteria and severity of the disorder, the two ethnic groups presented similar symptoms and degree of functional impairment. Both groups also showed significant improvement on self-report measures, parental reports, and clinician evaluations of Social Phobia and other aspects of psychopathology. Ethnic differences, however, were manifested in treatment outcomes, as indexed by clinical significance and responder status among the 29 children who completed treatment. At the end of treatment, 80% of the African American children but only 63% of their European American counterparts no longer met criteria for Social Phobia, a statistically significant difference. There was also an ethnic difference in treatment responders within the two groups, but in a direction opposite to that found for meeting Social Phobia criteria. Treatment responders were defined a priori as those meeting two criteria: posttreatment scores of less than 18 on the SPAIC and a rating of 8 or 9 on the Children's Global Assessment Scale (C-GAS; D. Shaffer et al., 1983), by an independent evaluator. Fifty-eight percent of European Americans met both criteria, whereas only 30% of African Americans did, a statistically significant difference. Because the two ethnic groups had virtually identical SPAIC scores, the observed ethnic difference was based primarily on C-GAS ratings by a clinician. The investigators suggested that the differential clinician ratings could be interpreted as indicating that the improvements shown by African Americans on the SPAIC were not

yet reflected in their behaviors or that there was a difficulty in judging problem severity when the observer and the person being observed came from different ethnic backgrounds.

Few studies have examined Anxiety Disorders among American Indians. Costello et al. (1997) reported that SAD was the most common Anxiety Disorder for both American Indian and European American youths living in Appalachia. Although rates for SAD were slightly higher for American Indians, especially girls, they were really similar for the two groups.

The only data on Anxiety Disorders among Asian American children and adolescents come from studies that used the Revised Child Anxiety and Depression scale (RCADS; Chorpita, Yim, Moffitt, Unemoto, & Francis, 2000), which measures symptoms associated with *DSM-IV* criteria for Anxiety Disorders and depression. Each RCADS subscale comprises empirically derived items. The total scale yields an internally consistent factor structure that corresponds to *DSM-IV* criteria for Social Phobia, separation anxiety, Panic Disorder and Agoraphobia (PDA), OCD, Generalized Anxiety Disorder (GAD), and depression (Chorpita et al., 2000).

Within the framework of the tripartite model of anxiety and depression (Clark & Watson, 1991), Austin and Chorpita (2004) examined temperament, anxiety, and depression in five ethnic groups of children and adolescents residing in Hawaii. In general, the results supported the tripartite model, but significant mean-level differences among ethnic groups were found for several specific anxiety dimensions. Native Hawaiians scored significantly higher on separation anxiety than their Filipino, Japanese, and European American counterparts. Both Native Hawaiians and Filipino Americans scored significantly higher on PDA and OCD than both Japanese Americans and European Americans. In addition, Filipino Americans scored significantly higher on Social Phobia than did European Americans. Last, Chinese Americans scored significantly higher on Social Phobia than Native Hawaiians and Filipino Americans. The investigators also examined the percentage of each ethnic group with clinically elevated scores on each of the six subscales of the RCADS (Chorpita et al., 2000). The percentages of elevated scores on the GAD subscale were fairly similar among the ethnic groups, but they were more variable on the other anxiety subscales. On both PDA and Separation Anxiety, Native Hawaiians and Filipino Americans had significantly higher percentages of clinical elevation than Chinese Americans, Japanese Americans, and European Americans. Significant ethnic differences were not found for

percentages of elevated scores on GAD, OCD, and Social Phobia. Austin and Chorpita interpreted these ethnic group differences in Anxiety Disorders as suggesting that factors outside of the tripartite model might explain the observed differences. Cultural norms and expectations might be one of those factors.

Data on Anxiety Disorders in Latino children comes from a study by Ginsburg and Silverman (1996), who compared Latino and European American youth ranging in age from 6 to 17 years. They found that Latino children were more likely to present with a primary diagnosis of SAD. Latino parents also rated their children as more fearful than did European American parents.

Depressive Symptomatology

Early research on ethnic differences in depressive symptomatology and mood disorders produced mixed results. As Roberts, Roberts, and Chen (1997) reported in their review of this literature, some studies reported that minority adolescents showed higher levels of depression and others found lower levels of depression (Doerfler, Felner, Rowling, Raley, & Evans, 1988). Still other studies found no ethnic differences at all (Kandel & Davies, 1982). Furthermore, variability among studies in the ethnicities sampled and the measures employed made it difficult to draw any firm conclusions from the findings.

Few studies have investigated depressive symptomatology in middle childhood among American ethnic minorities. Of those that did, a study of African and European American children in grades 3 to 5 revealed that a significant interaction between ethnicity and sex characterized the frequency of depressive symptoms (Kistner, David, & White, 2003). African American boys reported more depressive symptoms than European American boys, whereas the African American and European American girls had comparable levels. Sex differences in depression varied as a function of ethnicity. Among African Americans, boys were more depressed than girls, but among European Americans, girls were more depressed than boys.

The ethnic difference in depressive symptomatology noted during the third- through fifth-grade years may not necessarily persist in later years. D. A. Cole, Martin, Peeke, Henderson, and Harwell (1998) assessed depression and anxiety symptoms yearly in two cohorts of African Americans and European Americans from grades 3 to 5 and grades 6 to 8. African American children showed more symptoms of depression and anxiety in grades 3, 4, and 5 than did their European American peers. However, ethnic differences obtained from assessments conducted in grades 6, 7, and 8 did not reach a statistically significant level.

This finding raises the possibility that the role of ethnicity in depression may change over the years. Rushton, Forcier, and Schectman (2002) present some evidence suggesting that this may be the case. In an epidemiological study of depressive symptoms among adolescents who participated in the National Longitudinal Study of Adolescent Health, they found that ethnic minority youths (as well as females and older adolescents) were more likely to report depressive symptoms on the Center for Epidemiological Studies Depression Scale (CES-D; Radloff, 1977) than other participants at baseline, but race/ethnicity did not predict the manifestation of depressive symptoms 1 year later.

Perhaps different factors are associated with ethnic differences in depressive symptomatology at different ages. Some support for this hypothesis is provided by a longitudinal study (Gore & Aseltine, 2003) that examined changes in depression in a diverse urban sample over a 2-year period, beginning in the senior year of high school. This study showed that African Americans and Hispanics had higher scores on the CES-D scale than European Americans and Asian Americans. It also revealed that different factors were associated with these ethnic differences. College attendance accounted for the difference in depressive symptomatology between Asian Americans and African Americans or Latinos; the difference between European Americans and African Americans or Latinos was explained by the greater prevalence of problems in relations with peers and parents among the two ethnic minority groups.

Efforts to understand the link between ethnicity and depressive symptomatology include attempts to examine ethnic differences in depressive symptomatology associated with certain developmental transition points. In a study whose main aim was to assess ethnic differences in the association between pubertal status and symptoms of depression in three age groups of African, European, and Latino American adolescents, Hayward, Gotlib, Schraedley, and Litt (1999) found that among the gender/puberty status groups in their sample, African Americans did not show the same increases in depression symptomatology on the Children's Depression Inventory (CDI; Kovacs, 1985) from pre- to postpuberty that prior studies of European Americans had reported, whereas the Caucasian and Hispanic girls in their sample did. Hayward et al. interpreted this finding as suggesting that pubertal status is a better predictor of depressive symptoms than chronological age for European American girls, but not for their African American counterparts. Their findings, however, have to be taken as provisional because they were derived from a cross-sectional rather than a longitudinal sample. Ge et al. (2003) also ex-

amined changes in symptoms of depression associated with puberty in a sample of African American children assessed when they were approximately 11 years of age and again at approximately age 13. The results showed that pubertal effects varied as a function of gender and age. Among girls, early maturation was associated with higher levels of depressive symptoms at Time 1 and again at Time 2. Early maturing boys showed higher levels of depression at age 11 but not at age 13 years. Boys who experienced accelerated pubertal growth over time were more likely to have elevated levels of depression. This study provides partial support for the hypothesis that pubertal status is associated with depression in girls, but as there were no other ethnic groups involved, it does not settle the issue of whether pubertal status is better than chronological age at predicting depressive symptomatology in European American girls than in their African American counterparts (Hayward et al., 1999). Moreover, whether or not one finds a relationship between pubertal status and depression in African Americans may be related to other factors, such as depression in childhood. A. Shaffer, Forehand, and Kotchick (2002) conducted a longitudinal study of the correlates of depressive symptomatology in African American children (ages 6 to 11 years); they found that depressive symptoms predicted future adjustment problems.

Depressive symptomatology and mood disorders among American Indian children and youth have received relatively much less attention than have alcohol use, conduct problems, substance use, or smoking. Earlier, it had been reported that depression was the most common diagnosis for adolescent girls seeking help at the Indian Health Service mental health outpatient clinics (Beiser & Attnave, 1982). It has been hypothesized that the high rates of learning problems, Conduct Disorder, substance abuse, and running away among American Indian youth are consequences of depression (Choney, Berryhill-Paapke, & Robbins, 1995). Depression has also been considered a risk factor for suicide in this population. There are, however, conceptual and methodological issues that have yet to be resolved before culturally valid studies of depression can be undertaken. For example, the fact that the term "depression" cannot be directly translated into the Navajo language raises the issue of conceptual equivalence for that group. Also, studies that have examined the structure of depression in Native American samples have yielded findings that differ somewhat from those obtained with European American samples. Dick, Beals, Keane, and Manson (1994) examined the factor structure of the CES-D scale in a sample of American Indian adolescent students at a boarding school. They found that the depressed and somatic factors

were highly correlated and suggested that these two factors be collapsed into a single factor. In a more recent attempt to examine the structure of depression among American Indian youth, Rieckmann, Wadsworth, and Deyhle (2004) administered the CDI, two scales (Scale 2 and the Depressive Content Scale) from the Minnesota Multiphasic Personality Inventory, and the *DSM-IV* Questionnaire for Depression, a measure developed specifically for this study, to a random sample of 14- to 20-year-old Navajo youth stratified according to gender and grade (10th, 11th, and 12th). In this sample, the mean CDI total score was 10, slightly less than the cut-off score of 11 for determining depression (Kovacs, 1985). However, 14% of the participants exceeded the CDI cut-off score of 20 suggested by Kovacs (1992) for use with unselected or general samples. The model that best fit the data was a one-factor depression model that included four observed variables from the *DSM-IV* Questionnaire, total CDI score, and the Minnesota Multiphasic Personality Inventory-Adolescent (MMPI-A) Content and Clinical scales. The *DSM-IV* Questionnaire had the highest loading (.84) on the depression factor, followed by the CDI (.73) and MMPI-A Content (.68). The MMPI-A Clinical scale had the lowest (.28) loading. The investigators noted that among American Indian youth, symptoms of depression may also be manifested as stomach aches, other medical ailments, or even spiritual discontent and lack of harmony and balance, which may not be captured in the European American conceptualization of depression.

High rates for suicide or suicide attempts, often considered a correlate of depression, have been reported among American Indian youth. Recently, Freedenthal and Stiffman (2004) explored within-group differences in suicide rates as a function of geographical residence. Interviews of a stratified random sample of urban and reservation American Indian adolescents revealed that although urban and reservation youth reported comparable rates (14% to 18%) of suicide attempts, one-fifth of urban youth reported lifetime suicidal ideation, whereas one-third of reservation youth did. Urban youth had fewer psychosocial problems. Multivariate analyses conducted separately for each group failed to show common correlates of attempted suicide.

Studies of depressive symptomatology among Asian Americans are relatively few.

Using a 16-item scale abbreviation (Lin, 1989) of the CES-D, Greenberger and Chen (1996) assessed depressive symptomatology in a sample of 171 early adolescents and 297 late adolescents from Asian American and European American families. Ethnic differences did not emerge in the early adolescent sample; both ethnic groups reported

having a depressive symptom only once or twice a month. Within-group differences surfaced, however, in the Asian American group. Asian American early adolescents in the first or immigrant generation reported more symptoms than did their peers who were born in the United States. In the late adolescent group, Asian Americans reported significantly more frequent symptoms of depression than did European Americans. Furthermore, among the late adolescent Asian Americans, scores on depressive symptomatology did not differ significantly as a function of generational status. A microanalysis of depressive symptoms revealed significant ethnic differences on 4 of the 16 CES-D items. Asian Americans reported with greater frequency feeling "My life has been a failure." On average, Asian Americans reported feeling this way slightly more than once or twice in the past month, whereas the frequency for European Americans was midway between "never" and "once or twice." Asian Americans also indicated more disabling symptoms ("everything was an effort") and more difficulty in coping with distress ("could not shake off the blues" or "had trouble keeping my mind on things").

Also using the CES-D, Edman et al. (1998) assessed depressive symptomatology in Filipino Americans and European Americans ages 14 to 19 years who were from rural and small towns in Hawaii. No ethnic differences were found. The few Filipino American adolescents who reported having suicidal thoughts had moderately high to very high levels of reported depressive symptoms. Consistent with prior studies, females had higher CES-D scores. Edman et al. (1999) also examined the factor structure of the CES-D among Filipino adolescents. Two factors were found to provide a reasonably good fit to the data: Factor I was a combination of depressed affect, somatic-retardation, and interpersonal items; Factor II was composed of the remaining four items denoting positive affect. The combination of depressed affect and somatic symptoms in Factor I was interpreted as providing support for previous findings regarding an overlap between these two variables among Asian Americans. The loading of interpersonal items on Factor I is more unusual and, according to the investigators, suggests that interpersonal factors were not distinguished from depressed affect in this sample of Filipino adolescents.

As a first step in developing a reliable and culturally valid measure of depression in Korean Americans, Choi, Stafford, Meininger, Roberts, and Smith (2002) administered the *DSM* Scale for Depression (DSD; Choi et al., 2002) to a community sample of Korean Americans, ages 11 to 13 years, and compared their findings to the response

patterns of Korean and European Americans who participated in the Teen Life Changes Survey. Overall, Korean Americans had significantly higher depression scores than their European American peers. A correlational analysis of depression scores and scores for related constructs (loneliness, self-esteem, coping, social support, mastery, and somatic symptoms) showed the highest correlation to be between depression and somatic symptoms.

Information on symptoms of depression among Latino children comes from a methodological study and a meta-analytic study. In a study that examined the cross-ethnic equivalence of measures of negative life events and mental health (CDI, Child Hostility Scale, and the Global Self-Worth Scale) among 8- to 14-year-old Latino and European American children, Knight, Virdin, Ocampo, and Roosa (1994) found that the former scored higher on the CDI than the latter. The authors interpreted this ethnic difference to be a function of SES differences between the two ethnic samples, but they did not attempt an analysis that controlled for SES. A meta-analytic study, however, provides stronger evidence that the prevalence of depressive symptomatology may be higher in Latino youngsters than among their African American and European American peers. A meta-analysis performed on 310 samples of children and adolescents (ages 8 to 16; $N = 61,424$) by Twenge and Nolen-Hoeksema (2002) revealed that Latinos had significantly higher CDI scores than African Americans and European Americans. The mean scores of the latter two groups did not differ significantly from one another. The main and interaction effects of SES were not significant. Ethnicity did not have a significant effect on the stability of CDI scores, but gender did. For all three ethnic groups, girls' depression scores stayed steady from age 8 to 11 and then increased between ages 12 and 16. Boys' CDI scores were stable from ages 8 to 16 except for a high CDI mean score at age 12. Girls' scores were slightly lower than boys' during childhood, but girls scored higher beginning at age 13.

More studies of ethnic differences in depressive symptomatology and diagnosis have focused on adolescents. Depression in Mexican adolescents has been the focus of programmatic research by Roberts and his collaborators (Roberts & Chen, 1995; Roberts, Chen, & Solvitz, 1995; Roberts & Sobhan, 1992). Roberts and Sobhan reported that in a national survey of 12- to 17-year-olds, Mexican Americans reported more depressive symptoms on a 12-item version of the CES-D than did their peers of European, African, or other Latino origin. Males of Mexican descent had the highest rate. Their female counterparts

also showed high rates of depressive symptomatology, but to a lesser extent than did the males. Roberts (1994, cited in Roberts et al., 1997) found that middle school students of Mexican descent showed significantly higher rates of depression on the 20-item CES-D and the Weinberg Screening Affective Scale than their counterparts who were of European descent. Further analysis of the same data by Roberts and Chen revealed that adolescents of Mexican origin exhibited significantly more depressive symptomatology and suicidal ideation than the adolescent descendants of Europeans. The highest rates were found among females of Mexican origin. In both ethnic groups, depressive symptomatology and suicidal ideation were strongly related.

Siegel, Aneshensel, Taub, Cantwell, and Driscoll (1998) assessed the effects of race/ethnicity and gender in a multiethnic sample composed using a three-stage area probability sampling frame. Irrespective of socioeconomic status, Latinos reported more symptoms of depression than their European American, African American, and Asian American counterparts. Siegel et al. also investigated whether pubertal development influences depressed mood in a similar manner in gender and race/ethnicity groups. Advancing puberty was associated with depressed mood only among females, but the timing of pubertal changes, relative to one's peers, was related to depressed mood among both males and females and among Latinos.

Depressive symptomatology has been found among rural as well as urban Latino adolescents. In a study of 240 rural Latino adolescents, ages 15 to 20 years, Katragadda and Tidwell (1998) found that 33% of their sample showed moderate to severe levels of depressive symptomatology, and an additional 17% had mild depressive levels on the CES-D scale. Birth order and number of brothers were significantly related to depression. Gender was an important predictor of depressive symptomatology, as was self-esteem. Higher stress scores were also related to higher levels of depression.

Latinos have also been found to differ significantly from their counterparts in other ethnic groups in the prevalence of depression and alcohol use. Guiao and Thompson (2004) assessed the prevalence of depression, alcohol use, and suicidal behaviors in a random sample of 3,310 12- to 19-year-old females of Latino, African, American Indian, Asian, and European ancestry. Measures included the CES-D, number of drinks each time alcohol was consumed in the past year, and a composite measure of suicidal behaviors. Latinos were found to be at significantly higher risk for adolescent depression than the European Americans, and at higher risk for alcohol use than the African Americans and

Asian Americans. There were no significant ethnic differences in risk for suicidal behaviors. Latino middle school students may also be at greater risk for depression and substance use. Kelder et al. (2001) found depressive symptoms and substance use to be associated in a large sample of middle school students who were largely non-White and predominantly (59% to 63%) Latino.

The prevalence of depressive symptomatology in adolescents of Afro-Latino descent has also been explored. Ramos, Jaccard, and Guilamo-Ramos (2003) found that Afro-Latino adolescents in grades 7 through 12 residing in the United States exhibited higher levels of depressive symptoms than their European American, African American, and Latino counterparts. This finding suggests that descent from two ethnic minority groups increases the propensity to depression. Consistent with prior studies, this study also showed that, across ethnic groups, adolescent females had higher levels of depression than males, and older adolescents had higher levels of depressive symptomatology.

More recently, Sen (2004) reported that all minority groups who participated in the 1996 round of Health Behavior in School-Aged Children, a survey of 9,000 6th- to 10th graders constituting a representative sample, were more likely to suffer from depressed mood compared to non-Hispanic Whites, although Blacks were at lower risk for self-injury. Consistent with previous studies, adolescent females were more likely to present a depressed mood than adolescent males.

Depressive Disorders

Few studies have examined ethnic differences in mood disorders among ethnic minority children and youth. Most studies (e.g., Costello et al., 1996) have found few differences in depression between European Americans and African American youths. Roberts, Chen, and Solovitz (1995) investigated ethnocultural factors on the manifestation of *DSM-III-R* symptoms. In their sample of 334 Anglo, African, and Mexican Americans ages 12 to 17 years, 78 were diagnosed with Mood Disorder. There were few "meaningful" ethnic differences through a comparison of prevalence rates of symptoms and criteria for *DSM-III-R*, as well as rank order of criteria.

Among the few studies employing large samples, a study that assessed depression in nine ethnic groupings stands out. Roberts, Roberts, and Chen (1997) assessed depression in 5,423 students representing over 20 ethnicities in grades 6 to 8. For the entire sample, the mean prevalence rate for Major Depressive Episode (MDE) based on *DSM-*

IV criteria was 8.8% without adjusting for impairment and 4.3% with adjustment for impairment. These rates are higher than previously reported in the literature (Fleming & Offord, 1990). Analysis of the scores from the nine largest groups revealed that African Americans and Mexican Americans had significantly higher rates of MDE without impairment than European Americans and all other groups, but only the Mexican American group had significantly higher rates of MDE with impairment, independent of age, gender, and SES. Mexican Americans had the highest prevalence rate adjusted for impairment (6.6%); Chinese Americans had the lowest (1.9%). Consistent with findings from other studies, females overall had higher rates than males. A distinctive contribution of this study is that it examined the interaction between ethnicity and SES in a segment of the sample: European Americans, African Americans, and Mexican Americans. Neither chi-square analysis nor logistic regression analysis yielded a significant interaction effect on prevalence rates with or without adjustment for impairment. Across ethnic groups, prevalences were higher for those reporting lower SES.

Sack, McSharry, Clarke, and Kinney (1994) administered the Diagnostic Instrument for Children and Adolescents and selected sections of the Schedule of Affective Disorders and Schizophrenia for School-age Children-Epidemiologic Version, with the assistance of a Cambodian translator to a nonstratified random sample of 209 13- to 25-year-old Khmer adolescents and young adults; as well, a parent or guardian was interviewed in two Western communities to determine their diagnostic status following their survival of the Pol Pot War in Cambodia in 1975 to 1979. Roughly one-fifth of the adolescents, over half of the mothers, and about one-third of the fathers qualified for a current diagnosis of Posttraumatic Stress Disorder. There was high comorbidity with depression, but other forms of psychopathology were much less evident.

In an ethnically diverse sample of Asian/Pacific Islanders and European Americans, Austin and Chorpita (2004) did not find ethnic differences in depression, indexed through either average scores or percentage with clinically elevated scores, in their study of an ethnically diverse sample from Hawaii. Costello et al. (1997) did not find a significant difference in the rate of depression between Native Americans in Appalachia and their European American counterparts. Beals et al. (1997) reported that the 6-month prevalence rate of depressive disorders found in their sample of Plains Indian youths was essentially equivalent to the lifetime prevalence rate reported by

Lewisohn et al. (1993) for European Americans. It is worth noting that although these recent studies employing *DSM-III-R* have not found ethnic differences in the prevalence of depression among Native American youth, earlier reports suggested that depression is a problem in this population (Beiser & Attnave, 1982; Dinges & Duong-Tran, 1993). More recently, Rieckmann et al. (2004) reported that although the mean CDI score was 10, slightly below the 11 cut-off score for determining depression, 14% of their sample of 332 Navajo adolescents exceeded the CDI cut-off score of 20 suggested for use with general or unselected samples (Kovacs, 1992). It appears that higher rates of depression for Native American youths compared to their counterparts from other population groups emerge from self-report measures but not when *DSM-III-R* criteria for depressive disorders are applied.

In summary, this review found that most studies, including those with large probability samples, revealed some ethnic differences in prevalence rates of symptomatology or disorders among children and adolescents for conduct, substance-related, anxiety, and mood disorders. The presence of an ethnic difference varies as a function of the type of symptomatology or disorder and the ethnic group assessed. This conclusion differs from that presented in the 2001 supplement to the surgeon general's report on mental health that "within the United States, overall rates of mental disorders for most minority groups are largely similar to those of whites" (U.S. Department of Health and Human Services, 2001, p. 42). It is more consistent with the conclusion reached in a more recent review of adult mental disorders that "there is evidence that the various ethnic minority groups may exhibit significant differences in the prevalence of mental disorder" (Sue & Chu, 2003, p. 447). Our literature searches yielded many studies of the four disorders discussed; only the major ones were included in this review. It does not seem to be the case that "the smaller racial and ethnic groups, most notably American Indians, Alaska Natives, Asian Americans and Pacific Islanders are not sufficiently studied" (U.S. Department of Health and Human Services, 2001, p. 42), but rather that epidemiological studies of children and adolescents in this population are rare and community studies, although much greater in number, tend to concentrate on a few disorders or overly focus on a specific disorder when studying one group (e.g., substance-related problems among American Indian adolescents). A wider range of disorders need to be examined, preferably through epidemiological studies using large representative samples with adequate controls for relevant demographic variables.

CULTURAL CORRELATES OF CHILD PSYCHOPATHOLOGY

Some significant associations between psychological variables and symptomatology or disorder have been interpreted as possible reflections of cultural influences (Beals et al., 1997; Bird et al., 2001; Pina & Silverman, 2004). However, few studies have directly investigated the specific linkages between psychological variables (e.g., parental monitoring) and cultural variables (e.g., family closeness as a cultural value) or the role of cultural variables as risk or protective factors. In this section, we present findings on psychological variables associated with ethnic differences in psychopathology and discuss their observed or potential linkages to cultural variables. The role of cultural variables as protective or risk factors is also discussed. Culturally based protective and risk factors are not treated as mutually exclusive. Depending on the presence of other factors or circumstances, a cultural variable may function as a risk or as a protective factor.

Cultural Values

Each society has its own set of values or prized beliefs, concepts, institutions, and so on. These beliefs, concepts, institutions, practices, and so on are not necessarily unique to that society; they may be found in other societies. What is ethnic group- or culture-specific is the emphasis given to a particular belief, concept, or institution, the degree to which it is held dear or valued within a group. Cultural values are considered essential to the well-being of a society and its members. Each society seeks to maintain its values and to instill them in succeeding generations. It has been suggested that certain cultural values are related to development and mental health, either positively or negatively. In this section, we describe three cultural values that have been hypothesized as related to the mental health of ethnic minority youth and examine the evidence.

Family

In most societies, the family is the basic context for human development, including development gone awry. Families characteristics may vary, however, and culture is one source of variation. Cultural differences in family size, composition, structure, and dynamics can influence development. The extent to which they do is sometimes related to the cultural value attached to the family, and this value differs between individualist and collectivist cultures. In the former, individuals and personal goals are given priority

over groups and group goals; in the latter, groups such as the ethnic group or the family receive priority, and individual personal goals are subordinated to ethnic group or family goals. The family is considered important in both individualist and collectivist societies, but it receives a stronger emphasis and a higher priority among collectivist cultures, such as those of African Americans, American Indians, Asian Americans, and Latinos. "Familismo" or "familism" are the terms, introduced by Latino researchers, applied to this emphasis on the family, which many consider a mediator variable through which culture influences normal or pathological development.

In regard to conduct problems, one study of academic misconduct in community samples showed that although early adolescent European Americans, Chinese Americans, Taipei Chinese, and Beijing Chinese displayed comparable overall levels and types of self-reported misconduct (academic misconduct, antisocial behaviors, status violations), the relative contributions of family and peers to misconduct differed significantly among the groups (Chen, Greenberger, Leiter, Dong, & Guo, 1998). Family variables were parent-adolescent conflict, parental warmth, and parental monitoring; peer variables were peer approval and peer sanctions for misconduct. Structural equation modeling using only the data from adolescents showed that family relationships and peer sanctions for misconduct accounted for a significant amount of variance in misconduct for all four groups, but the percentage of variance accounted for was much greater for the two American samples than for the two Chinese samples from Asia. The cross-national difference was due mainly to the greater contribution of peer factors to adolescent misconduct among European Americans and Chinese Americans. Structural equation modeling that included data from mothers did not significantly change the proportionate contributions of family and peer factors to adolescent misconduct. Chen et al. suggest that the relatively stronger influence of peers may be due to the fact that American adolescents spend more time with their peers than do their counterparts in Taipei or Beijing.

Family relations and parental monitoring were among the significant predictors of the higher levels (3 = lying, disobedience, 4 = damaging property, attacking someone) of antisocial behavior for three groups of children and adolescents, Island Puerto Ricans and Mainland African Americans and European Americans (non-Hispanic Whites), but not for Mainland Hispanics, possibly due to the small sample size of this group (Bird et al., 2001). Island Puerto Ricans had lower rates for all three levels of

antisocial behavior compared to the three Mainland groups (Hispanics, African Americans, and non-Latino, non-African Americans who were mostly European Americans). Bird et al. also examined the rate of increase (or decrease) in antisocial behavior involved for each of the correlates. Only poor relationships with other members of the family were associated with a substantial increase in antisocial behaviors. Because this variable was significantly lower for Island Puerto Ricans than the three Mainland ethnic groups, Bird et al. concluded that the only finding that stood out as an explanation for the lower rates of antisocial behavior among Island Puerto Rican participants could be accounted for by the association between lower levels of antisocial behavior and better family relations. Although they carefully noted that causality cannot be inferred from a finding obtained in a cross-cultural study, they still asserted that it is, potentially, of cross-cultural importance.

Additional research among Island Puerto Ricans is needed to confirm the role of better family relations as a protective factor against the development of antisocial behavior and to identify other factors that might augment or support its role. Bird et al. (2001) suggest that two such factors might be direct parental control through discipline (Patterson, 1982, cited in Bird et al., 2001) and social control (Hirsch, 1969, cited in Bird et al., 2001). In a collectivist society such as is found in Puerto Rico, strong family attachments are valued and promoted. There are also clear societal and family expectations of what are appropriate behaviors and the sanctions for violations. Direct parental control is exercised through discipline without the coercion that can impair parent-child relationships. At the same time, social control is facilitated by large extended families that, along with parents, monitor and supervise the behavior of children, adolescents, and young adults. In addition, the expectations and sanctions may also be endorsed by other societal institutions such as religious organizations and schools, creating a sense of societal congruence that increases social control. Bird et al. suggest that the levels of direct parental control and social control may have eroded for Mainland Puerto Ricans, who were more like the other Mainland ethnic groups. If erosion has indeed occurred, one contributing factor might be the peer group, as suggested by the Chen et al. (1998) study. Studies are needed to confirm this and also to test the hypothesis that strong family attachments, direct parental control through strict but noncoercive discipline, and social control by extended family members and other socialization agents may prevent the emergence of antisocial behaviors.

Thus far, there is scant evidence for the role of culturally based family variables as correlates of substance use/abuse. Although Costello et al. (1997) reported that some family variables were associated with psychiatric disorders in their sample of American Indians and European American youth living in Appalachia, these do not appear at face value to be culturally based family variables. For both groups, family mental illness appears strongly associated with childhood disorder. Poverty, family deviance, and, to a lesser extent, family adversity were associated with child psychiatric disorder in the European American sample, but not in the American Indian sample. Although Costello et al. did not investigate cultural factors as possible correlates of substance abuse among American Indian youth, other investigators have done so.

Beals et al. (1997) noted that the elevated rates of substance use disorders, specifically alcohol abuse/dependence noted in their sample of American Indian youth, appeared to reflect the elevated rates present among adults in their community and suggested that cultural factors could be among the many reasons for these rates. However, Beals did not specify any culturally based family variables. In the absence of evidence for such variables, the co-occurrence of elevated rates of substance use in both the youth and adult communities might be accounted for in terms of social learning, in some cases building on a biologically based predisposition or "vulnerability to alcoholism" (Ehlers, Garcia-Andrade, & Phillips, 2001; Wall, Garcia-Andrade, Wong, Lau, & Ehlers, 2000). Within their families and communities, youth may observe substance use with few sanctions against it. Acquisition may actually occur within the peer group and be maintained by it. An assessment of the contexts associated with drug use among American Indian adolescents of the Southwest revealed that the most frequent and difficult (i.e., perceived difficulty in resisting use) drug and alcohol situations occurred primarily with cousins or friends at home or after school (Okamoto, LeCroy, Dustman, Hohmann-Marriot, & Kulis, 2004). Last, although it has been hypothesized that how native groups drink has been conditioned by aspects of their respective social organization (families and communities) prior to the advent of Europeans in the New World, Spicer, Novins, Mitchell, and Beals (2003) failed to find evidence for this hypothesis. Their study of four contemporary American Indian groups showed that cultural group differences accounted for a small percentage of the variance in both the quantity and frequency of alcohol use and its negative consequences, but the patterns of alcohol use were not consistent with the hypothesis that they would be related to

aspects of American Indian social organizations prior to European colonialism.

The family as a mediator of culture's influence on internalizing disorders has also been studied by researchers. Ginsburg and Silverman (1996) found support for the hypothesis that separation anxiety would be greater in those ethnic groups that highly value the maintenance of close family relationships and interdependence. The higher rates of SAD among Hispanic children are surprising given a prior suggestion in the attachment literature that children from cultures that have large extended families with multiple caregivers might be less prone to separation anxiety. However, the Latino children studied by Ginsburg and Silverman were more likely to come from families with lower incomes than their European American counterparts. Perhaps they were children from low-income immigrant families who lacked the extended kinship support available in their country of origin while attempting to deal with a new environment. Furthermore, these children might have experienced periods of separation from one or both parents during the process of migration. Because measures of attachment or family closeness were not administered, one cannot conclude that the significant difference in the prevalence of SAD between the two samples can be explained by cultural differences in attachment or family closeness.

Austin and Chorpita (2004) found only partial support for their hypothesis that separation anxiety would be higher in those ethnic groups that place a high value on maintaining close family relationships and interdependence. Although this hypothesis was confirmed for Native Hawaiians based on their mean RCADS score, and for both Native Hawaiians and Filipino Americans based on percentages with clinically elevated RCADS scores, it was not true for the Chinese and Japanese Americans. Because Austin and Chorpita did not actually administer a measure of family closeness and interdependence, it is difficult to explain their findings. Perhaps the assumptions underlying their hypothesis need to be reviewed. Separation anxiety is characterized by developmentally inappropriate anxiety around separation from the home or from one or more attachment figures. It is associated with persistent and excessive worry about losing or being separated from an attachment figure, or about possible harm befalling an attachment figure (American Psychiatric Association, 2000). Implied in these characteristics is a sense of insecurity in the child. Does family closeness necessarily breed insecurity? Or does it actually do the opposite, instill a sense of security that emboldens the child to explore the environment, secure in the knowledge that there is a home base or

safe haven to which he or she can return? Perhaps there are varying types of family closeness with different developmental outcomes. Furthermore, strategies for maintaining family closeness and interdependence may have differential developmental outcomes: Some may instill a sense of security, whereas others do not; some may achieve a balance between interdependence and independence that enables the child to feel confident that he or she can function without the constant presence of the attachment figure, whereas other strategies may foster a greater dependence that makes a child feel insecure in the absence of a major attachment figure. The developmental cross-cultural literature on families and attachment (e.g., Harwood, Miller, & Irizarry, 1995) might be helpful in reconceptualizing the relationships among family closeness, interdependence, and separation anxiety.

Depressed mood in late adolescence has been found to be associated with problems in relations with parents, as well as with peers. Based on a 2-year longitudinal study, Gore and Aseltine (2003) reported that 2 years after high school, the difference between European Americans and African Americans or Latinos in depressed mood was accounted for by problems in parental relations and peer relations. In contrast, the difference between Asian Americans and African Americans or Latinos was accounted for by lower college enrollment.

Before leaving this discussion of the family as a possible mediator of the relationship between culture and psychopathology, it should be noted that even when studies find cross-cultural consistency in the relationships between family variables and depressive symptoms among children (Kim, 2000) and adolescents (Dmitrieva, Chen, Greenberger, & Gil-Rivas, 2004), they also reveal cross-cultural differences in the magnitude of associations among variables. This finding underscores the importance of looking beyond surface similarities to distinguish what is culturally specific from what is universal.

Simpatia

Varela et al. (2004) tested the hypothesis that anxiety reporting would be associated positively with the cultural value of *simpatia*, a Spanish construct denoting empathy with others and remaining agreeable even if it entails self-sacrifices (Gabrielidis, Stephan, Ybarra, Pearson, & Villareal, 1997, as cited in Varela et al.; Kagan & Madden, 1970, as cited in Varela et al., 2004). *Simpatia* is emphasized more in collectivist than in individualist cultures. To ascertain that the participants did indeed have a collectivist orientation, Varela et al. assessed this. As expected, Mexican and Mexican American children endorsed collec-

tivism as a cultural value more than did European Americans. They also exhibited a greater use of strategies reflecting *simpatia*. In addition, support was found for a direct link between the reporting of physiological anxiety and *simpatia*.

Interpersonal Relations and Social Conformity

Cultures vary in the value they place on interpersonal relations and adherence to group norms for interpersonal relations. Some support for the hypothesis that there is a relationship between these values and anxiety was obtained by Austin and Chorpita (2004). Based on prior research (Okazaki, 1997) they predicted that Chinese, Japanese, and Filipino American youths whose ethnic groups assign greater negative attributions and shame to violations of norms for interpersonal interaction would have higher mean scores and higher rates of clinical elevation on social anxiety than those with other ethnic affiliations. This prediction turned out to be correct for Chinese Americans and Filipino Americans, but not for Japanese Americans, but only in regard to RCADS mean scores on social anxiety. Although the percentage of Chinese Americans with clinically elevated scores was the highest among all ethnic groups in the diverse sample, the difference was not statistically significant.

Ethnic Socialization

Ethnic socialization is the process whereby parents and other elders in an ethnic group transmit their culture to the younger generation and also prepare them for interacting with other ethnic groups. Thus, it includes enculturation or the task of cultural transmission and what is sometimes referred to as racial socialization. Ethnic socialization for dealing with racial issues has been suggested as a possible correlate of anxiety among African American children. Neal-Barnett (2004) has hypothesized that African American parents who prepare their children to deal with racial stressors may be providing them also with a protection against the development of anxiety and depressive symptoms. Among African Americans, ethnic socialization for racial issues may involve minimizing the gender socialization that is found in other ethnic groups. S. F. Lambert, Cooley, et al. (2004) found that, unlike studies of European American children, their study did not reveal sex differences in anxiety sensitivity among African American children. They interpreted this finding as an indication of a possible lack of gender differentiation in ethnic socialization. According to S. F. Lambert, Cooley, et al.,

low-income African American families and schools in urban communities characterized by high levels of hostility and violence may minimize gender differences in socialization to provide girls as well as boys with knowledge and skills required for staying safe in these communities that present an “ecological risk” (Prelow, Danoff-Burg, Swenson, & Pulgiano, 2004).

Ethnic socialization has been invoked to account for the observed ethnic differences in anxiety-related somatic and physiological symptoms and distress associated with these symptoms. According to Pina and Silverman (2004), the difference between European American and Hispanic/Latino youth in anxiety-related somatic complaints is attributable to Latino socialization, or more specifically, observational learning and reinforcement. Parental reactions to their own somatic/physiological symptoms (e.g., refraining from daily activities such as going to work) serve as models for coping with such symptoms. Children experiencing distress may then also develop somatic or physiological complaints. Parental reactions to their children’s somatic complaints such as allowing them to stay home from school or giving them extra attention, special foods, or get-well gifts reinforce or increase the probability of recurrence of the children’s displays of and ideas about the meaning of somatic/physiological symptoms.

Pina and Silverman (2004) did not assess ethnic socialization for expression of anxiety symptomatology. However, observational data on parents’ explanations for ambiguous events in family discussions from the Varela et al. (2004) study illustrate how such ethnic socialization might take place. This study yielded support for the hypothesis that Mexican and Mexican American parents would model avoidance of anxious interpretations to potentially threatening situations because these situations could evoke aversive feelings. In talking with their children about solving ambiguous problem situations, Mexican parents generated fewer anxious, nonsomatic interpretations than their European American counterparts. Another hypothesis was also confirmed: Mexican and Mexican American parents did encourage and model somatic, nonanxious interpretations to ambiguous problem situations, probably because expression of emotions in somatic form is more culturally acceptable. In parent-child discussions, Mexican and Mexican American parents generated more somatic, nonanxious (or nonpsychological) interpretations than did European American parents. Additional support for the hypothesized link between culturally based family processes and anxiety reporting in children of Mexican descent was provided by a positive correlation between a parent somatic

interpretation index and children’s scores on the Worry scale of the RCMAS. Although ethnic socialization may begin during childhood among those of Mexican descent, a clear preference for somatic explanations of internal ambiguous symptoms or ambiguous social stimuli over anxiety-related interpretations may not be manifested until late adolescence or adulthood, after long-term exposure to cultural mediums (e.g., media, school, peers) that endorse this attribution style (Varela et al., 2004). Thus, parents of Mexican descent would be more likely than their children to show a somatic bias.

Acculturation

The developmental and other outcomes of ethnic socialization can be altered through acculturation, the process of learning about the culture of another ethnic group, when acquired knowledge, attitudes, and behaviors are incorporated into the individual’s behavioral repertoire. Pina and Silverman (2004) suggested acculturation as a possible explanation for the differences in reporting of somatic/physiological symptoms of anxiety that they found between subgroups of Cuban American versus non-Cuban Latino Americans and within the non-Cuban group, between those whose parents preferred English as the assessment language and those who chose Spanish. According to these investigators, youth with Hispanic origins whose parents preferred English as the assessment language might have been more acculturated and adopted European American ways of conceptualizing and expressing distress. Hence, their children responded more like European Americans than members of their ethnic group whose parents preferred Spanish. Acculturation was not directly assessed in the Pina and Silverman study, so research is still needed to examine its role as a correlate or predictor of anxiety-related somatic and physiological complaints for Latino youth.

Lacking data on acculturation, Pina and Silverman (2004) suggested that in their study, language choice could have served as a proxy variable for acculturation (Angel & Guarnaccia, 1989). If English as the preferred language is a proxy for acculturation and the choice of Spanish is a proxy for less acculturation, then there should have been no difference between the Cuban Americans and non-Cuban American Latinos in the Spanish language choice group. However, this was not the case. Among those who chose Spanish, Cuban American youth reported somatic/physiological symptoms as significantly more distressing than did non-Cuban American Latino youth. As an alternative explanation, Pina and Silverman proposed that language

choice, independent of acculturation level, may still serve as a cultural signifier for reporting psychosocial or psychological distress, including anxiety (Reichman, 1997, as cited in Pina & Silverman, 2004). Research is still needed to examine the role of acculturation in the expression of anxiety and the role of language choice as a proxy for acculturation or as an independent cultural signifier for reporting psychosocial or psychological distress.

At least one study has investigated the relationship between acculturation, childhood depression, and coping. Huang, Leong, and Wagner (1994) assessed the effects of self-esteem and perceived competence on children's perceived stressors, dysphoria, and coping strategies in Chinese American children differing in levels of acculturation. For both acculturation groups, peer stressors were significantly related to feelings of dysphoria. Children's choice of coping strategy differed as a function of acculturation. Consistent with traditional Chinese teaching, low-acculturation children most effectively used suppression in dealing with daily life stressors, whereas high-acculturation children were more likely to use retaliation. Still, retaliation was the least commonly used coping strategy among highly acculturated children. In contrast, low-acculturated children used their most effective strategy—suppression—frequently.

Acculturative stress, that is, perceived stress from the experience of attempting to reconcile cultural differences, has been linked to depressive symptoms. In a study of Mexican American middle school students, Romero and Roberts (2003) found that for both immigrant and native-born Mexican American youths, higher perceived acculturative stress was associated with predepressive symptoms. Immigrant youths reported a higher total number of stressors than did native-born Mexican Americans. The sources of stress also differed between the two groups. Native-born Mexican Americans reported more stress from needing better Spanish-language skills and from the impact of their parents' culture or intergenerational gaps whereas immigrant youths perceived more stress from needing better English proficiency in school.

Ethnic Identification

A study of ethnic pride, biculturalism, and drug use norms of urban American Indian adolescents in seventh grade (age 11 to 15 years) has shown that students who have a more intense sense of ethnic pride adhere more strongly to certain antidrug norms (Kulis, Napoli, & Marsiglia, 2002). In another study, ethnic pride was associated with differential outcomes for different ethnic groups. Marsiglia, Kulis,

and Hech (2001) found that African-American, Mexican-American, and mixed-ethnicity students with a strong sense of ethnic pride reported less drug use and exposure, whereas European-American students who also took great pride in their ethnicity reported more.

Among adults, the strength of identification with an ethnic group is directly associated with fewer depressive symptoms (Mossakowski, 2003). In a sample of African American children ages 10 to 12 years, community ethnic identification was negatively related to depressive symptoms (Simons et al., 2002). There was also evidence that community ethnic identification mediated the relationship between victimization and depressive symptoms.

Ethnic identity is manifested through cultural orientation. In a study involving 9th- and 11th-grade Asian American students ages 14 to 19 years, cultural orientation and interpersonal relationships were significant predictors of depression (Wong, 2001). Subjects with a high orientation toward ethnic culture and a low orientation toward mainstream culture experienced greater depression than those with high orientation toward American culture and low orientation toward ethnic culture. In addition, the presence of more positive parent and peer relationships predicted lower depressive levels. None of the examined demographic variables was a significant predictor of depression, although subjects who immigrated after the age of 12 years were more depressed than U.S.-born adolescents.

Mental Health-Related Beliefs

One of the pathways whereby culture might indirectly influence the emergence and persistence of psychopathology is through an ethnic group's shared beliefs about mental health. The culture of an ethnic group includes beliefs about typical and atypical behaviors, explanations for deviance, and what constitutes significant impairment of functioning. Although a number of studies have assessed ethnic differences among college students and adults in their beliefs about various psychological problems or disorders (e.g., Luk & Bond, 1992), few have done so among children or adolescents and their parents. McKelvey, Baldasar, Sang, and Roberts (1999) found that a large proportion of Vietnamese parents in an Australian community sample attributed a child's mental illness to biological/chemical imbalance, trauma, and metaphysical or spiritual causes. Other studies involving children or adolescents who had been diagnosed and/or were receiving mental health services have yielded inconsistent results. Yeh, Hough, McCabe, Lau, and Garland (2004) asked the parents of 1,338 youths with identified mental health

problems about the causes of their children's problems. Beliefs about 11 etiologies fell into three major categories: biopsychosocial, sociological, and spiritual/nature disharmony causes. Parents of African American, Asian/Pacific Islander American, and Latino American children were generally less likely than parents of non-Latino Whites to endorse etiologies consistent with biopsychosocial beliefs about mental illness. These biopsychosocial beliefs included physical causes, personality, relational issues, familial issues, and trauma. Some racial/ethnic differences were evident for sociological causes such as friends, American culture, prejudice, and economic problems. No ethnic differences were found for beliefs in spiritual or nature disharmony etiologies. Analyses controlling for demographic characteristics, child's symptomatology and problem severity, and public service sector affiliation produced fewer significant racial/ethnic differences but a similar pattern of results. These analyses also showed that compared to European American parents, African American parents were less likely to attribute mental illness to relational issues or spiritual issues; Asian/Pacific Islanders were less likely to report physical causes, personality, familial issues, and trauma as causes; and Latinos were less likely to endorse physical causes, personality, relational issues, familial issues, and American culture. Unlike European American parents, African Americans and Asian/Pacific Islanders were more likely to endorse prejudice as a cause and also were more likely to attribute their child's problem to American culture. The authors concluded that racial/ethnic differences in parental beliefs about the causes of their child's problems exist in an at-risk sample.

Another study that employed a sample of children who had been identified as having a disorder was conducted by Bussing, Schoenberg, Rogers, Zima, and Angus (1998). These investigators explored the explanatory models of ADHD held by parents representing two ethnic groups. They reported that whereas European Americans were more likely than their African American counterparts to use medical labels as descriptors for their child with ADHD, the two groups did not differ significantly in their etiological or causal explanations for the disorder. Perhaps the lack of ethnic differences reported by Bussing et al. is a function of their having used two groups of parents whose children essentially had the same disorder. Yeh et al. (2004) found that after controlling for child symptomatology, African American parents did not differ from European American parents in their beliefs about biopsychosocial causes of mental illness, except that they were less likely to attribute mental illness to relational issues.

These findings denoting similar beliefs about a syndrome in parents from different ethnic groups whose children have been diagnosed suggests that cultural beliefs about a syndrome can be altered through exposure to the beliefs of other cultures.

Some support for this suggestion is provided by a British study of beliefs about depression held by two age groups (17 to 28 years and 35 to 42 years) of native-born British and Asian-born immigrants to Britain (Furnham & Malik, 1994). In the middle-aged group, Asian-born participants differed significantly from native-born British in their perceptions of the symptoms and causes of depression. In the younger group of late adolescents and young adults, however, Asian-born immigrants who grew up in Britain did not differ from their native-born British peers. It appears that cultural beliefs about a syndrome are learned during the formative years (Furnham & Malik, 1994). The broader cultural context of concept formation plays an important role; exposure to a different culture during the formative years results in the acquisition of that culture's beliefs about a syndrome even if one's parents hold different cultural beliefs. There is also evidence that cultural beliefs about a syndrome acquired during the formative years are retained in adulthood, even if one immigrates to a country with a different culture (Furnham & Malike, 1994). A new, broader cultural context may not bring about an alteration in cultural beliefs unless accommodation becomes necessary. Change can occur if one's child develops a syndrome that requires direct contact with mental health professionals who hold different cultural beliefs about that syndrome and impart those to the parent (Bussing et al., 1998; Yeh et al., 2004). The nature of how specific alterations occur remains unknown. Is it a case of substitution or integration? Does a change in beliefs about one syndrome result in a change in the pattern of organization among cultural beliefs related to mental health?

Cultural Responses to Deviance and Distress

Cultural beliefs about psychological problems or disorders are important because they set the parameters for threshold tolerance of and responses to atypical or deviant behaviors from the individual and the environment. A longitudinal study of stress-buffering effects for urban male African American adolescent problem behaviors and mental health revealed that although parental support predicted less anxiety and depression longitudinally, the manifestation of psychological symptoms did not predict increased parental support over time. In other words, high parental support may protect African American youth from anxiety and depres-

sion, but the appearance of symptoms does not necessarily activate increased levels of support in this ethnic group.

Help Seeking and Preferred Modes of Intervention

Ethnic differences in help seeking have been reported. Based on data from the 1996 round of Health Behavior in School Children, Sen (2004) reported that certain racial groups are at greater risk for not asking for help for depression. In a study of the mental health needs and service utilization of 401 southwestern urban and reservation youth, Stiffman, Striley, Brown, Limb, and Ostmann (2003) found that, regardless of diagnosis, youth meeting criteria for a mental disorder were least likely to use configurations with traditional healers or specialists, and there was little difference in their utilization rates of either. Instead, they were more likely to use service configurations including adults, nonspecialist professionals, and peers before turning to specialists. Sen (2004) found that Black and Asian adolescents were especially prone not to ask for help, with the problem being more acute in the case of males in both groups. The majority of males and females with depressed mood or self-injury risk were not likely to seek help from anyone.

Abe-Kim, Gong, and Takeuchi (2004) examined the influence of religious affiliation, religiosity, and spirituality on help seeking from religious clergy and mental health professionals among 2,285 respondents to the Filipino American Community Epidemiological Survey. After controlling for need (e.g., Symptom Checklist-90 Revised [SCL-90R]; Derogatis & Cleary, 1977; scores, negative life events, and somatic symptoms), demographic variables (e.g., age, gender, marital status, education, county of residence, generational status, and insurance coverage), and cultural variables (e.g., loss of face and language abilities), rates of help seeking from religious clergy (2.5%) were comparable to rates of help seeking from mental health professionals (2.9%). High religiosity was associated with more help seeking from religious clergy but not less help seeking from mental health professionals, whereas high spirituality was associated with less help seeking from mental health professionals.

Experiences with mental health professionals can affect service utilization. Diala et al. (2000) found that, prior to use of services, African Americans had more positive attitudes than European Americans toward seeking such services, though they were less likely to use them. After utilization, however, African American attitudes were found to be less positive than those of European Americans.

Ethnicity, Minority Status, and Perceived Discrimination

Although not a cultural variable, ethnic minority status and its correlates, such as perceived discrimination and low socioeconomic status, with its increased likelihood of exposure to community violence, are often associated with psychological problems and cannot be ignored.

Relationships between these variables and symptomatology or disorder have been found. The ability to perceive racial/ethnic discrimination changes with increasing age. Among Mainland Puerto Ricans, children had a low likelihood of perceiving discrimination, but by adolescence, nearly half of this sample reported perceiving racial/ethnic discrimination (Szalacha et al., 2003). Adolescents were aware of negative stereotypes about Puerto Ricans. Although both groups scored high on multiple indicators of mental health, perceiving discrimination and worrying about discrimination were negatively associated with some dimensions of self-esteem and positively associated with depression and stress. Perceived discrimination and anxiety about discrimination can serve as risk factors for the mental health of Puerto Ricans. Phinney, Madden, and Santos (1998) examined whether perceptions of discrimination may be influenced by one's interpretation of the intentions of others. They studied a sample of Armenian, Mexican American, and Vietnamese adolescents (ages 14 to 19 years) who completed measures of perceived discrimination, self-esteem, mastery, depression/anxiety, intergroup competence, and ethnic identity, as well as demographic variables. A path analysis of the data showed that higher depression/anxiety scores and lower intergroup competence predicted more perceived discrimination. Depression/anxiety and intergroup competence were in turn predicted by self-esteem and mastery, respectively. Birthplace and socioeconomic status had an important effect on perceived discrimination via intergroup competence. Last, Simons et al. (2002) reported that for their sample of African American children (ages 10 to 12 years), at the community level, prevalence of both discrimination and criminal victimization were positively related to depressive symptoms.

CONCEPTUAL AND METHODOLOGICAL ISSUES

Doubts about the conceptual equivalence of certain constructs used in studying internalizing disorders have been

raised by several investigators. S. F. Lambert et al. (2004) and Neal-Barnett (2004) have questioned the relevance of the construct anxiety sensitivity for African American children living in high-crime areas. According to these authors, the construct may not have the same meaning and usefulness for this population as it does for other ethnic groups because high anxiety sensitivity may serve as a protective factor and therefore is actually an adaptive strategy in that environment. Given that physical concerns emerged as a robust first factor in the CASI structure for this population, it would seem that the construct of anxiety sensitivity remains meaningful and relevant for African American children and, as shown by S. F. Lambert, McCreary, et al. (2004), for adolescents. However, norms for anxiety sensitivity in this population may be different from those of other ethnic groups or for low-income African-American children living in high-crime areas. This suggests the need to include an assessment of context such as environmental stressors when employing measures such as the FSSC-R and CASI with all children living in poor neighborhoods riddled with crime and other environmental hazards.

Given the overlap of depression with anxiety, somatoform, and dissociative disorders, Kirmayer and Groleau (2001) have raised questions about the universality of the prototype representation for depression in North American psychiatry. They note that culture-specific symptoms may lead to underrecognition or misidentification of syndromes of mania and depression in many ethnocultural groups. Cultural idioms of distress may employ symptoms related to affective disorders to express sentiments and perceptions that do not in themselves indicate psychopathology. A similar concern can be expressed regarding anxiety. Some inconsistent findings on somatic/physiological symptoms of anxiety discussed in this review indicate the need for rethinking the representation of anxiety as well. If increased reporting of anxiety symptoms is the result of cultural influence, as it appears to be at some level, then normative patterns of anxiety reporting in certain populations need to be established and the cultural meaning of such reporting needs to be investigated further.

Much of the extant *cross-cultural* research compares national groups or ethnic groups and implicitly makes the term *culture* equivalent to a label for a sample of subjects (e.g., American versus Chinese). Each person in a given sample is indexed as belonging to a particular national or ethnic group and sharing that group's culture; thus, culture is treated as an index variable (Valsiner, 1997). The problem is that an index variable is a poor substitute for an independent variable that can be manipulated in order to

determine its causal relationship to the dependent variable. A persistent methodological problem in studies of cultural diversity in psychopathology is the omission of measures of the assumed cultural basis of the hypothesized ethnic difference. This makes it difficult to reach any definite conclusion about the role of culture. For example, if a collectivist culture is assumed to value family closeness, which, in turn, is hypothesized to serve as protective factor for depression, it would be desirable to include a measure of collectivism in addition to a measure of family closeness. Family closeness may exist for reasons other than that it is culturally valued. The inclusion of data on collectivism strengthens the inference of a cultural basis should the hypothesized association between family closeness and depression be confirmed.

Sampling is another methodological weakness in these studies. Aside from the problem of small sample size in a number of studies, there was ambiguity as to whether the sample was a random sample or the degree to which it was representative of the population being studied. Social class and other relevant characteristics such as generational status were sometimes not reported. Although more studies were careful to use distinct ethnic subgroups (e.g., Cuban Americans) and took this into account in the data analysis, others did not and gave no justification for their use of a heterogeneous ethnic group (e.g., Latinos).

In studies of prevalence rates for disorders whose behavioral indices sometimes overlap with those of other disorders (e.g., somatic symptoms present in both anxiety and depression), comorbidity was not analyzed. Last, many of the measures used are not normed for the population studied. In general, the approach taken in these studies has been an *etic* rather than an *emic* approach. Such an approach is not very effective at detecting cultural diversity.

CONCLUSIONS AND FUTURE DIRECTIONS

Cross-cultural studies indicate that certain disorders are identifiable in different countries in various regions of the world, using the same nosology and measures. They also show that gender differences in prevalence rates appear, regardless of that country's view of gender roles and socialization. With rare exceptions, such as the work of Weisz and his collaborators (1997), the cross-cultural studies reviewed in this chapter focused on prevalence rates and measurement validation rather than the cultural correlates of a disorder. Research is needed to investigate culture's role in the development of specific disorders, as well as in

their persistence or desistance. This could be incorporated, for example, in the cross-cultural programmatic research on problem behaviors in Dutch children and adolescents by Verhulst and his colleagues (Verhulst & Achenbach, 1995; Verhulst et al., 1997).

Whereas cross-cultural studies did not reveal much evidence of cultural diversity in prevalence rates, comparative ethnic studies did. Ethnic differences in rates of symptoms or *DSM* disorders emerged from epidemiological studies and community and clinical samples. What is notable about these findings is that no one ethnic group showed higher rates across disorders. Rather, one ethnic group may have consistently higher rates than other groups for a particular disorder (e.g., depression among Latinos, substance use/abuse in American Indians) but had rates comparable to those of other groups for other disorders. Furthermore, within-subgroup differences in prevalence rates emerged, indicating the importance of examining ethnic group differences by using ethnic subgroups rather than panethnic groups such as Latinos or Asian Americans, unless prior research has revealed similar findings across subgroups of a panethnic group. Subgroup differences may eventually disappear with succeeding generations also, but until such time as there is solid evidence of similarities across subgroups, findings from a comparison of panethnic groups should be treated with caution. Cross-cultural and cross-ethnic studies that examined the factor structure of specific constructs measured (e.g., fear or anxiety) consistently showed cultural group differences.

Given the paucity of epidemiological studies, the methodological limitations, and, in some cases, inconsistent findings from community and clinical studies, any conclusions about ethnic differences in prevalence rates would be premature. Still, there is sufficient evidence to warrant additional research, preferably involving large representative samples. Prior to undertaking epidemiological studies, more work is needed to ascertain the ways psychopathology is defined in various cultures (Hoagwood & Jensen, 1997), including cultural variations in symptom expression and phenomenology of psychiatric syndromes (Manson, Bechtold, Novins, & Beals, 1997). Despite its acknowledgment of culture's role in psychopathology, the nosological system (i.e., *DSM-IV-TR*) applied currently in cross-cultural research still conceptualizes mental disorder mainly as residing in the individual sans context. Such a nosological system itself emerged from an epistemology that is culturally constituted. The likelihood of finding differences in prevalence rates among other cultural groups may be restricted by the diagnostic criteria and measurement tools employed. To fully understand the relationship

between culture and psychopathology, behaviors that are assumed to be psychopathological (usually culturally defined in Western societies as a *DSM* disorder) have to be explored from other culturally constituted epistemologies. In addition, other culturally constituted expressions of psychopathology have to be explored.

What is initially required is an emic approach. Ethnographic or observational studies to identify and classify cultural variations in the expression of distress or psychopathology can provide data for hypothesis generation, to be followed by more formal, hypothesis-testing research. Other exploratory studies using qualitative, ethnographic, and narrative methods can be used to obtain data for construct definition and identification of culturally appropriate indices as well as correlates that, in turn, can serve as a basis for measurement construction and generation of hypotheses. Quantitative studies using larger, representative samples to establish the psychometric properties of measures and norms would follow. In case the results of exploratory studies suggest that an etic approach would be appropriate in that existing measures might be suitable, the factor structure of relevant constructs (e.g., anxiety) or patterns of organization for symptoms or behavioral indices of a disorder still need to be examined. In addition, it will have to be determined whether the measure fully captures the range of relevant problems or behavior indices of a specific condition in the culture under consideration; if it does not, items will have to be added and the psychometric properties of the revised instrument must be established.

The importance of using reliable, culturally valid measures normed for the specific population cannot be overemphasized. More careful consideration should be given to the following questions: To what degree is what we find the result of measures that are predicated on premises of our dominant, culturally constituted epistemology? If we have developed a measure with samples dominated by majority culture participants and then apply these measures cross-culturally, and find little difference in prevalence and little variability in the expression of, for example, anxiety, what does this finding mean? By defining, via the measurement instruments, what anxiety is in the majority European American culture, there is likely to be a restriction of what we allow ourselves to find, and this will increase the likelihood that the disorder will look the same everywhere. Also, to what degree are our methods of analysis, our statistics, affecting what we find? For example, is our reliance on mean differences very informative? Might mean differences be obfuscating other important information that bears on the issue of the role of culture and, more generally, context in the development of psychopathology? Al-

though approaches that disaggregate the data and look for different patterns of variability are important in examining cultural differences, we need to also explore quantitative methods that are not part of our current statistical repertoire, such as fuzzy logic, which has been used in some cognitive applications. Developmental psychopathology cross-cultural/ethnocultural research can benefit from interdisciplinary collaborations.

Our review of studies on cultural correlates of psychopathology indicated that the same disorder may be associated with different correlates in different ethnic groups or cultures. Furthermore, for a given correlate, the magnitude of associations or the pattern of relationships may differ among different ethnic groups. For the same ethnic group, the magnitude of association between specific symptomatology or disorder and a correlate (e.g., ethnic identity) may vary, depending on how the correlate is operationalized or the age at which the relationship is being assessed.

A developmental-contextual perspective seems lacking in most of the studies reviewed. Culture's role may undergo changes over time, just as in historical time (Bronfenbrenner, 1995) a cultural attribute may change its adaptive function for an individual. Given the lack of sufficient empirical data, it is difficult to predict the direction of the change. It could increase with the individual's increasing age if there is congruence between the individual's ethnicity and that of the surrounding community, or weaken if the dominant culture is different. Changes in the relationship between culture and psychopathology may also depend on the specific cultural and developmental variables involved. Only a few studies have examined age-related changes in culture's role, and longitudinal studies are practically nonexistent. More cross-sectional studies, followed by longitudinal studies, are needed to more precisely elucidate the influence of culture on normal and atypical development and its interaction with other correlates in the course of development.

Culture's role has not been sufficiently explored in the development of any symptomatology or disorder reviewed in this chapter, so there is clearly a need for more research on this issue. However, more thoughtful consideration of the relevant cultural variables and processes ought to precede our choice of cultural variables to study and the disorders that they are hypothesized to influence. It is conceivable that culture may play a less prominent role in the development of those disorders that tend to be reproductive (e.g., Autism) rather than caretaking (e.g., Conduct Disorder) casualties (Sameroff & Chandler, 1975), while continuing to have a strong impact on societal responses to both disorders. Furthermore, the assumptions underlying

our hypotheses need to be based on adequate theoretical or empirical knowledge about both the disorder (e.g., separation anxiety) and the hypothesized cultural correlate (e.g., family closeness). Certain cultural constructs (e.g., family, ethnic identity) require unpacking or further differentiation into their various aspects. The salience of context and time of assessment may have to be taken into consideration. For example, ethnicity may not be found to be salient if assessment is conducted in routine activities at various times of the day; ethnic differences in problem behaviors may not be observed if data are collected at home or in the neighborhood but will appear in school. Perhaps the lack of ethnic differences in prevalence rates for certain symptomatology or disorders may be due partly to the fact that so many ethnic minority children and youth with these problems do not participate in research because they are disproportionately in foster homes, residential treatment centers, juvenile detention, or jail, or are just simply out on the streets.

As stated in the introduction to this chapter, culture is relevant to an understanding of psychopathology because of its role in development and because it shapes environmental response to distress and atypical behavior. Though culture may not play a prominent role in the development of certain disorders, it may still do so in shaping the environment's response to the emergence of those disorders. There are few studies on the latter role pertaining to the problems of children and adolescents. More work is needed, including studies to determine beliefs about the etiology, prognosis, and treatment of specific clinical syndromes, help-seeking attitudes and preferences, and expectations of treatment held by both the parent and the developing child or adolescent. There is much to be learned in the relationship of context, including culture, to the development of psychopathology, and we are only beginning to get a better appreciation of the importance of this relationship.

REFERENCES	667

A multifaceted, context-linked, and systems-oriented human development perspective is essential for a maximized understanding of *resilience* and *vulnerability*; in fact, a carefully nuanced approach is particularly needed when considering broad ethnic enclaves and, more generally, all humans' normative pursuit of stage-specific life

course competencies. The perils that youth face, along with the successful and unsuccessful strategies they employ in coping with these risks, must be understood both in relation to their maturational and identity formation statuses and as linked to the larger social, cultural, and historical contexts of development. Research efforts in

developmental psychopathology and applied human development have increasingly focused on risk and resilience. Scholars have begun exploring important conceptual issues that require greater clarity, such as the various definitions of resilience as a construct, and the utility of these in various contexts (e.g., see Luthar, 2003; Luthar & Cicchetti, 2000; Luthar, Cicchetti, & Becker, 2000; Spencer, 2001). A key point to add to this discussion is that risk and resilience cannot be separated from normative developmental processes that occur in multiple contexts. Healthy and normal human development involves *negotiating some level of stage-specific threat* (i.e., given available and honed competencies of salience to the risks confronted) and *demonstrating a degree of resilience* (i.e., successful outcomes) in the face of challenge.

From our perspective, risk is properly conceptualized as the exacerbation of normative challenges encountered in the pursuit of myriad stage-specific competencies and is linked to broad sociopolitical processes (i.e., racism, sexism) and/or lack of resources (e.g., see Gallay & Flanagan, 2000). Protective factors such as social (e.g., cultural capital) and material (e.g., the intergenerational transmission of wealth) resources help individuals to cope with exacerbated normative challenges and, thus, maximize available supports. We define vulnerability as the net experience of risk and protective factors that an individual encounters (see Anthony, 1974). Productive as well as unproductive coping outcomes are possible. Accordingly, as an outcome, resilience involves successful negotiation of exacerbated challenges; however, resilience is not possible without significant challenge being encountered and is associated with heightened risk conditions.

RESILIENT OUTCOMES: LINKAGES WITH CONTEXT, CHARACTER, AND COPING NEEDS

From a service provider perspective, Leon Chestang (1972b) suggests that American culture and social policies are infused with discrepancies concerning what is wanted and expected from citizens of color. He postulates that, on the one hand, *competence, social responsibility, and independence* are desired as life course outcomes. However, independent of the developmental period of concern and efforts made, there remain significant and built-in obstacles to the achievement of those outcomes.

Spencer (2001) describes the consequences of structural racism for minority youth as, at minimum, a twofold blow. First, youth of color frequently live and mature in high-risk contexts characterized by systemic, structural barriers to

individual success. More specifically, these obstacles include conditions in the neighborhood, family, and school contexts, and interactions among these different contexts; additionally, challenges emanate from relationships between these settings and the larger social, economic, and political forces in U.S. society more generally. In fact, Kochman (1992) suggests that there are particular individual-context conditions. In a thorough and broad review, he describes communities where children grow and adults attempt to meet their needs although they are confronted by consistent patterns in the social structural conditions that make goals for competence and productive citizenship virtually impossible. More to the point, Kochman suggests that specifically African American communities are frequently distinguished by crowded conditions, hazardous waste facilities, and other high-risk environmental elements that seldom appear in affluent and suburban communities. Of salience is that these conditions collectively increase stress, decrease one's ability to cope, diminish the sense of community and psychological mutuality, and result in increases in behavior problems that compromise competence. As illustrated by Emmy Werner's (1989; Werner & Smith, 2001) classic studies, many youth manage good outcomes and demonstrate resilience; however, generally speaking and as suggested by standard journal publications and textbooks, when considering mainland youth of color, the mediating processes between risk factors and resilient outcomes are infrequently unpacked when considering ethnic minorities.

From our perspective, a significant contributor to the unpacking of mediating processes evident between risks and resilient outcomes has been Brewster Smith's (1968) classic theorizing about competence formation. DeCharms's (1968) ideas aid and complement Smith's, which together enhance our understanding of resilience. Specifically, DeCharms suggests that an *individual's primary motivational propensity is to be effective in producing changes in his or her environment to make a (positive) impact by making a difference*. Although conceptually similar to Smith's and to Robert White's (1959) views concerning competence formation and effectance motivation, DeCharms's theorizing goes a step further. DeCharms describes his construct as one of *personal causation*, which implicitly reinforces the salience of human agency. His perspective suggests that psychosocial processes (i.e., demonstrating personal agency) are fundamental for productive outcomes and stage-specific competencies. The classic ideas put forth by White, DeCharms, and Smith complement each other. Considered together, the conceptual formulations (1) provide accompaniment to James Anthony's

(1974) insightful notions concerning resiliency, (2) afford additional essentials to the race-specific and culturally sensitive contextual perspective of Leon Chestang (1972b), and (3) highlight the person-process context insights made available by Bronfenbrenner (1989). Collectively synthesized, these theorists provide a dynamic and synergistic conceptual formulation that is foundational for Spencer's (2001) suggested second component or outcome that she hypothesizes emanates from structural racism. Specifically, she suggests that the many instances of resilience—success and competence displayed by vulnerable youth in spite of adverse living conditions—often go unrecognized, thus *denying individuals a sense of agency, success, and inferred accomplishment*. Importantly, the oversight forgoes the potential and positive protective factor function of *acknowledged resiliency*. Instead, by ignoring the fact of race and ethnicity linked negative social structural conditions and associations with resiliency, the omission further compromises individual coping and allows the continued interpretational liberties about youth of color that frequently and narrowly label their lives and efforts as suggesting solely deviancy, pathology, deficits, and problems.

Spencer's (2001) synthesis suggests that youths' manifested resiliency should still be associated with future psychological fragility that requires sustained support during subsequent developmental periods and for the critical transitions in between (see Spencer, 2001). To illustrate, a single dose of early intervention against inequitable life course conditions administered during the preschool years *alone*—perhaps as Head Start programming—is inadequate. “The inoculating impact is ineffective given the chronic and multidimensional expressions of structural racism as one moves forward across the life course” (p. 35). As suggested by Anthony (1974), all youth are psychologically vulnerable. However, low-risk environments may offset the manifestation of high vulnerability, whereas chronic high-risk environments may virtually guarantee it. In other words, even in the face of high risk, protective factors may promote generally positive outcomes, stage-specific competencies, and resiliency. The work by Werner and colleagues (Werner, 1989, 2000; Werner & Smith, 2001) with indigenous Hawaiian children quite clearly demonstrates the point.

As described by Cook and Cook (2005), it is heartening to observe children doing well when everything is working for them; however, it is more impressive to see youth doing well when the odds appear insurmountable. Programs of research on resilient children—children who succeed, achieve, or otherwise have positive developmental outcomes despite growing up under negative condi-

tions—have been addressed for youth generally by researchers such as Garmezy (1985), Luthar et al. (2000), and Rutter (1987). However, an identity-focused and context-linked scholarly emphasis on resilience, particularly when considering diverse youth of color, has been a long-term focus of Spencer and colleagues (e.g., see Spencer, 1983, 1984, 1985, 1986, 1987).

Our approach to human development, and thus to vulnerability, risk, and resilience, represents an *identity-focused, cultural-ecological* perspective. We focus on identity statuses that confer either privilege or marginality and consider factors including race and gender. We examine and infer how these factors affect several dimensions of human coping: individuals' perceptions of self and future opportunities; imposed expectations, such as stereotypes that result from inferences about race and gender; and the interaction between these various influences and normative development processes such as physical maturation and identity formation. Furthermore, we emphasize the need to understand these issues as they are impacted by multiple levels of context. This includes both proximal contexts—immediate situational settings such as school, family, and neighborhood—and distal contexts, that is, broad societal influences including political decisions and media messages that are filtered through the more proximal venues. The interactions among these different settings and hierarchical levels of context should also be recognized as they impact human development processes, risk, and resilience.

In this chapter, as an organizational strategy for understanding development in context, we present Spencer's (1995, in press) phenomenological variant of ecological systems theory (PVEST). The identity-focused, cultural-ecological framework of normative human development significantly enhances the examination of resilience and vulnerability among youth. Accordingly, first, we consider major conceptual flaws that have marred research on racially and ethnically diverse youth. We highlight how these conceptual flaws have led to misunderstandings about resilience and vulnerability. Next, we present several theoretical correctives to these flaws in an effort to build toward our comprehensive, racially and culturally sensitive model of human development. We discuss the major theoretical traditions that PVEST builds on, including Erikson's and Marcia's theorizing on identity, racial identity theories, symbolic interactionism, and Bronfenbrenner's ecological systems theory. Subsequently, we lay out the PVEST model and apply it to understand both the unique and patterned challenges—or the absence of major difficulties—faced differentially by racially and ethnically diverse youth. Broader societal factors and histori-

cal processes that contribute to the vulnerability of youth are considered; these include structural dimensions of racial inequity, ideological manifestations such as colorism and racial stereotypes, racial/ethnic privilege, and the challenges faced by immigrant youth. We consider how this vulnerability filters through to the everyday lives of youth by discussing experiences of racial stereotypes, attitudes, and negotiation of cultural dissonance, using selected examples to cover these points. Also contemplated are the implications of racial/ethnic experiences for youths' coping strategies, identity formation, and stage-specific outcomes. Finally, we discuss the implications of all of these factors for resilience among racially and ethnically diverse youth. Our conclusion considers, integrates, and addresses these issues and presents additional theoretical themes salient for resilience and vulnerability.

CONCEPTUAL FLAWS IN RESEARCH ON RACIALLY AND ETHNICALLY DIVERSE YOUTH

Historically, several recurring conceptual flaws have characterized research on racially and ethnically diverse youth (Spencer & Harpalani, 2001; Spencer, Noll, Stoltzfus, & Harpalani, 2001; Swanson, Spencer, et al., 2003). First and foremost, in general, discussions about youth of color have often lacked a developmental perspective. African American youth specifically, and male adolescents in particular, are treated as miniature or short adults rather than as progressively complex young people growing and developing in myriad settings given unavoidable maturation processes occurring across domains of human functioning. The frequently static and decontextualized approach applied to youth of color, although compared with outcomes achieved by middle-income and Caucasian youth, further exacerbates interpretational errors and perpetuates stereotyping assumptions applied to both groups. More specifically, pathology assumptions taint the interpretations and assumptions made about the former group (i.e., youth of color), on the one hand, while privileging expectations protect the latter group (i.e., Caucasian youth), on the other. As noted, researchers should not only be cognizant of these assumptions, but should also explicitly address issues of normative development in their research conceptualization and design (Swanson, Spencer, & Petersen, 1998).

Our point is that youth of color are often viewed as non-normative or pathological. On the other hand, as suggested and given an unquestioned position of privilege, the current majority group in this country, White Americans, is often held as the normative standard by which all other groups

are judged. This situation is inferred from most research and implicit in the training of developmental scientists because the issue appears too uncomfortable to either acknowledge as an issue or remedy as a deterrent to inclusive science. In fact, it appears that even when diverse youth are included in programs of research, the perspective taken continues to be deficit dependent at best and pathology focused at worst. Accordingly, for youth of color, particularly African American male youth, normative developmental experiences are not considered or, in general, are misunderstood. The prevailing deficit-oriented perspective focuses on negative outcomes and ignores the resilience demonstrated by many youth of color given the group's consistent encountering of hostile, although generally unacknowledged, contextual experiences (see Chestang, 1972a, 1972b). At the same time, the perspective generally ignores the privileging experiences persistently enjoyed by middle-income and White youths more generally (see McIntosh, 1989). The perspective taken also fails to see the behavior and coping strategies of these youth in light of normative developmental challenges; this is the case whether the given behaviors and coping strategies reactively deployed are adaptive or maladaptive. Deficit-oriented perspectives also overlook the critical function of perceptual processes in normal cognitive maturation and, thus, misinterpret how *youths themselves* make meaning of their own experiences. Such perspectives thus frequently merely substitute assumptions of cultural deficiency (e.g., Fordham & Ogbu, 1986). Racism, manifested through structural and ideological dimensions, is often coupled with economic challenges and other barriers, all of which frequently characterize the environments encountered by minority adolescents (Swanson & Spencer, 1998). The experiences of these youth should be viewed in light of these phenomena—as responses to adverse conditions of stress rather than cultural characteristics. These factors affect adolescent perceptions of self, other, and future life prospects; they therefore require consideration, but without demonizing through stereotyping and pathological inferences imposed about the youth themselves.

It is also important to consider multiple, hierarchical levels of context when examining the experiences of youth. Too often, context is ignored altogether, and even when it is considered, measures of context refer only to immediate, situational influences or settings, such as schools or families, rather than the entire interwoven nexus of historical, political, and societal influences that impact these immediate settings and the interactions among them. A more thorough, theoretically driven view of contextual influences on human development is necessary to understand

not only resilience and vulnerability, but the entire realm of experiences and psychosocial attitudes and behaviors of racially and ethnically diverse youth. Such an analysis buttresses the use of resilience as the classification for productive outcomes for some (i.e., those experiencing persistent and significant challenges) versus those whose productive outcomes are due to the consonance (i.e., consistency of experiences) between contextual character (i.e., communicated positive expectations and patterned support) and the sets of stage-specific normative challenges associated with particular developmental periods. That is, we profess the conceptual position that the latter situation and noted stage-specific productive coping outcomes do not necessarily suggest resilience but, instead, indicate *productive coping efforts and outcomes that are the result of significant supports provided in response to normative developmental challenge*.

Finally, a lack of cultural competence is another related flaw in scholarship on youth of color. In a paradoxical way, this is particularly relevant to research on racially and ethnically diverse youth. Ethnic minority status may, on the surface, prompt the researcher to consider issues of culture and context; however, scholarship lacking a comprehensive theoretical framework of normative human development often obscures the most salient issues for particular groups rather than illuminating them (see discussion by Lee, Spencer, & Harpalani, 2003). The behavioral outcomes of youth of color are often analyzed simplistically using culturally deterministic formulations that ignore within-group variation. Conversely, researchers often assume that cultural factors are unnecessary to consider; thus, they are conveniently overlooked in the experiences of White youth. This penchant undermines the field's embrace of culturally competent analyses and encourages a perspective that suggests that culture applies only to youth of color and is associated narrowly with deficit points of view. As suggested, this approach not only neglects salient issues, but also implicitly *pathologizes* the experiences of youth of color by normalizing White youth's developmental experiences (see Spencer, in press). Of particular importance, cultural competence is not merely of clinical and therapeutic relevance: It is a critical factor in the design and interpretation of research. In sum, cultural competence promotes scientific research that is proficient in its incorporation and consideration of culture. As described by Lee et al., adolescents from diverse backgrounds have a variety of understandings of family, school, and neighborhood experiences that cannot be understood with traditionally simplistic, media-hyped, and nonnormative cultural formulations (e.g., Fordham & Ogbu, 1986); such shortsightedness under-

mines the design, production, and application of good science. Although culturally nuanced perspectives are necessary to understand social and psychological experiences of diverse populations, such an understanding of necessity must also include careful attention to assumptions about normative developmental experiences (Swanson, Spencer, et al., 2003).

MITIGATING CONCEPTUAL SHORTCOMINGS IN RESEARCH: CORRECTIVE STEPS

To address traditional shortcomings in research on racially and ethnically diverse youth, we propose several key steps. All are related and employed to assist in building toward the PVEST.

Normative Human Development Perspective

First, a normative human development perspective should be employed when examining resilience and vulnerability among all youth. As noted earlier, we view risk and resilience as integrally tied to normative developmental processes. The experiences of youth should be viewed in terms of such processes and challenges, including those associated with physical maturation, identity formation, negotiation of relationships with peers and elders, and other situations that require youth to employ problem-solving strategies in response to *normative and nonnormative* stage-linked challenges. For youth of color, these challenges are often exacerbated; for example, for second-generation Asian American youth, navigating peer and family relationships may be compounded by extensive cultural dissonance across family and school settings; for African American youth (males in particular), physical maturation must be negotiated in conjunction with media-propagated negative stereotypes of Black male criminality. The important point is that all of these challenges should be understood as part of normative development in adolescence; although issues such as stereotyping and cultural dissonance may contribute to and exacerbate normative challenges, the experiences of youth of color should not be viewed separately from normative developmental issues. Moreover, we should keep this issue in mind whether we are considering adaptive or maladaptive behaviors by these youth because the behaviors as reactive coping strategies are associated with contextual experiences linked with broad and frequently exacerbating experiences (i.e., for

some) as described. Without that admonishment, differences in outcomes accrued both within and between groups are naïvely characterized.

Thorough and Nuanced Integration of Context

Context considerations require careful integration when analyzing the experiences of racially and ethnically diverse youth. Moreover, this should occur not in superficial ways, but in a manner that incorporates all levels of contextual influence. For example, Van Oers (1998) notes that context is often defined improperly in empirical literatures. Often, context is used to refer merely to situational influence, ignoring information processing and meaning making, which translate situational influence into perception-linked interpretation and action. Van Oers argues for a more dynamic approach to the defining of context, one that takes into account these processes and is more accurately described in terms of action (i.e., “contextualizing”) rather than static influence. Additionally, Dannefer (1992) describes four components of context: physical setting, social interactions, developing person, and time. Beyond these considerations, it is important to recognize how larger societal biases and historical influences filter through into everyday life and potentially permeate youths’ daily experiences. Accordingly, beyond merely placing the experiences of young people in their immediate, situational contexts, there are conceptual benefits to placing these immediate situational settings in their larger social context and, thus, for considering the implications for youth.

Focus on Resilience in Conjunction with Normative Human Development

There should be a focus not only on problem behavior, but also on resilience, the attainment of positive outcomes among high-risk youth who are confronted with significant, persistent, and frequently nonnormative challenges. The notion of resilience, along with the challenges in studying it as a phenomenon, enjoys broad interest. It has been addressed in detail by Suniya Luthar and Dante Cicchetti (Luthar & Cicchetti, 2000; Luthar et al., 2000) and Margaret Beale Spencer (Connell, Spencer, & Aber, 1994; Spencer, 2001; Spencer, Cole, Dupree, Glymph, & Pierce, 1993; Swanson & Spencer, 1991) and their colleagues. Spencer’s early work frequently and specifically highlighted African American youth, although more recent research and application include ethnically diverse samples. We build on all of this work to raise several points.

In conjunction with a normative developmental perspective and an emphasis on multiple levels of context, researchers would benefit from analyzing risk and resilience in terms of process, rather than traits. This allows social scientists to consider and integrate perceptual processes that can be employed to help children overcome barriers and access available supports (Spencer, 2001). As youth develop and interact with elders and peers, their perceptions and behaviors change with social and cognitive development. They move from having an egocentric to a more sociocentric view of their world as they develop into more social beings. This conceptually multifaceted approach that simultaneously considers and integrates multiple domains of human development in fact improves our understanding of the manner in which social, cognitive, and maturational development can affect children’s perceptions of their immediate and larger worlds. Insights accrued also explain how these developments interact with significant others in different settings that vary as to levels of context and, consequently, their implications for risk, resilience, and vulnerability. Researchers should recognize the developmental plasticity inherent in these phenomena, so as not to assume that particular risks will lead to negative outcomes and that youth cannot employ active strategies to avoid or minimize their exposure to risk. We opine that such thinking is inherently narrow and deterministic and implies that environmental factors are intransigent, unable to be altered by human effort.

The use of certain terminology further suggests a focus on macrosystem influence over individual-level agency. In fact, there have been recommendations for researchers to revise their use of terminology, using the term *resilience* rather than *resiliency* to refer to positive adjustment within challenging contexts, rather than a personal attribute (Masten, 1994). Such a change reflects a move to embrace the transactional nature of resilience. A criticism of using the term *resiliency* is that it can be associated with a personality trait, and therefore suggests that children are born with (or without) the skills necessary to overcome challenge (Luthar, Cicchetti, & Becker, 2000). It therefore implies that children do not engage in transactions with different elements of their environments and have no independent ability to influence their contextual surroundings to decrease or increase the amount of risk and protection around them. With this in mind, risk and resilience involve dynamic processes, not predetermined traits, and they emerge as a result of constant interactions between children and factors in their environments (Luthar et al., in press; Masten, 1994).

The same argument can be applied to the use of “at risk”; the term has historically been applied to youth who are disproportionately exposed to risk factors at various levels of proximity. Even though children living amid numerous challenges may contend with high amounts of environmental stress, they may simultaneously benefit from having availability and access to numerous supports in their immediate contexts; their availability and accessibility may offset the negative effects of risk and increase children’s abilities to exhibit resilience. When the words “at risk” are used to describe youth themselves rather than the high-risk environments in which they live, this suggests, at best, that these children have little autonomy in overcoming challenge and avoiding negative outcomes. Even worse, the association of “at risk” with youth of color has contributed to the perpetuation of negative stereotypes assigned to them, which in turn has led to negative assumptions about their abilities to exhibit success under adverse conditions.

Authentic and Dynamic Consideration of Cultural Influences

Our view is that culture should be understood as a dynamic system and way of living, not as a static entity. Traditionally, culture has been defined as a “complex whole” (e.g., Tylor, 1871/1958, p. 1) or a set of routine practices within a particular socially and historically located group (Cole, 1996). Classical ideas of culture have also been critiqued and expanded on. In analyzing the notion of culture, Gilbert (1989) notes that psychological constructs are often unequipped for describing dynamic processes. In the modern world, rapid social change has become characteristic of all domains in society; thus, the construct of culture is difficult to define. Gilbert proposes a definition as a set of control mechanisms, with individuals acting as self-reflexive agents responding to cultural forces and social change. Segall (1984) has criticized efforts to create a universal definition of culture. He contends that the focus should be on identification of salient ecological, sociological, and cultural variables that influence human behavior. According to Segall, the identification of these variables, rather than a strict, universally applicable definition of culture, is central to theoretical advances in cross-cultural psychology.

Building on these ideas, we propose the analysis of cultural influences in a process-oriented manner—to focus on cultural socialization and the learning of these practices, along with their meaning to the individual (Lee, Spencer,

& Harpalani, 2003). As noted by Ingold (1994, p. 330), “People live culturally rather than . . . live in cultures.” Conceptualizing and understanding cultural influences in this way can help mitigate the pitfall of *cultural determinism* and inherently emphasizes the changing nature of cultural practices, at both individual and group levels.

Related to these issues, both etic (general to all cultural groups) and emic (specific to a particular cultural group) perspectives on socialization and human development are important (Garcia Coll, Akerman, & Cicchetti, 2000). One of our major points has been the importance of normative developmental processes and experiences (as understood by the outside observer) as common to all youth. Additionally, we recognize that the meaning attributed to these experiences (and thus the subjective developmental phenomena from the individual’s perspective) may vary according to social, historical, and cultural context and be influenced by more proximal factors.

Nuanced Consideration of Race and Ethnicity

Researchers and practitioners should acknowledge the complexity of race and ethnicity and view these phenomena from multiple perspectives: in terms of cultural differences, structural racism, and normative developmental processes such as racial identity formation. Each of these areas is derived from a different disciplinary source—cultural differences from anthropology, structural racism from sociology, and racial identity formation from psychology—and they are seldom integrated into a single body of scholarship. Nevertheless, to properly understand the normative development of racially and ethnically diverse youth, an integrative approach *indicative of a multidisciplinary human development perspective* combining these areas is essential.

With regard to race, our perspective emphasizes the individual’s everyday experiences and perceptions; thus, we focus on *how (the salience of) race is lived on a daily basis* and how individuals, including developing youth, make meaning of these experiences. Experiences of race are filtered through larger societal influences, such as manifestations of structural racism (see Bonilla-Silva, 1997), as illustrated by residential and economic segregation, and by encounters of negative stereotypes in the media and in everyday life. It is also necessary to clarify the application of terms such “race” and “ethnicity,” which are often used interchangeably. Generally, the former refers to perceptions of observable phenotype, and the latter refers to cultural background. At times, it is useful for researchers to

focus on ethnicity; for example, the culturally specific family experiences of African Americans and African immigrants may differ. However, of salience is that given the more difficult task of discerning facts of culture, youth from both groups may experience similar racial stereotyping and treatment based on the common denominator of color and identifiability (see Spencer, in press). Depending on the particular circumstances, it may be more useful to focus on one or the other. It is also important to note that many youth and adults perceive their racial and ethnic backgrounds as interchangeable, if not identical, and these are often intricately linked in identity formation. Thus, at times, it may be useful to consider race and ethnicity together, and it is always important to understand how the two interact in shaping the everyday experiences of racially and ethnically diverse youth (for an overview, see Fisher, Jackson, & Villarruel, 1998, pp. 1157–1166; Spencer, in press).

Additionally, it is worth explicitly stating that “racially and ethnically diverse” includes White; if it did not, this would only contribute to the normalization of Whiteness. White youth, like all others, must be studied as one of many diverse groups. Although youth of color are disproportionately represented among the low-economic-resource populations, many White youth are also in this group. The socioeconomic stressors faced by all of these youth may be similar, although low-income Whites typically are not residentially segregated and have greater access to financial resources (through family connections, etc.) than people of color (Conley, 1999; M. L. Sullivan, 1989). Additionally, White youth and youth of color face the same basic developmental challenges; the primary difference between the two is that White youth are considered to be the norm and reap all of the privileges of this status, ranging from greater cultural consonance experienced across school, family, and neighborhood settings to “racial invisibility” (i.e., minimal race-based stereotyping) in everyday encounters. Nonetheless, because the challenges faced by all racially and ethnically diverse youth, generally, and youth of color, more specifically, overlap to an extent, we are nuanced in our use of terminology. We refer differentially to youth of color (designating all non-White youth), low-economic-resource youth (designating those of all race/ethnic backgrounds whose families meet particular socioeconomic criteria such as federal poverty guidelines), marginalized youth (youth from both of the aforementioned categories and others, such as lesbian, gay, bisexual, and transsexual youth, who are accorded lower status on the basis of identity), and all racially and ethnically diverse youth, depending

on the specific developmental issues and challenges being discussed. At times, we also refer to specific racial/ethnic groups, particularly African Americans, to illustrate challenges.

As a function of their net vulnerability and stress levels experienced, *the specific and patterned strategies that youth of color employ to cope with life experiences afford the basis for the formation of identity*, including racial/ethnic identity. As noted, this process occurs both in the larger social context of American society and in the more local contexts of family, school, and neighborhood that youth encounter. Our major point here is that the processes of coping and identity formation are developmentally contingent; they depend on youths’ prior experiences and previous coping responses and identities. There is also a need to examine gender identity in interaction with race. Studies of gender identity often yield significant racial and ethnic differences; for example, Parker et al. (1995) note that Black and White adolescent girls think about body image ideals in very different ways. Confounding factors create complex interactions between race/ethnicity and gender.

Phenomenological Perspective on Identity and Self

It is also critical to employ a process-oriented phenomenological perspective in research on youth—to understand how youth understand *their own worlds*. Studies that have overlooked the importance of youth phenomenology have resulted in misinterpretation, as perceptual processes are essential to a full understanding of behavioral outcomes. For example, the interpreters of the program of research by Clark and Clark (1939, 1940) erroneously assumed that children of color needed to respond as Caucasian children did in order to be considered “healthy” and “normal”; thus, scholars and policymakers misinterpreted the self-esteem of African American youth (see Spencer, 1982b, 1984). Such misinterpretation results largely from comparing outcomes among youth of color to Eurocentric expectations. It is important not only to appreciate how youth of color contend with unique risk factors, but also to acknowledge normative developmental responses to these conditions. This can be accomplished only through a phenomenological viewpoint.

As suggested by Bandura’s (1978) theorizing, self-system development is reciprocally determined from self/other appraisal processes (Spencer & Dupree, 1996). Self-appraisal processes integrate various aspects of one’s life that promote identity formation; these represent social, cognitive, and affective dimensions. As perceptions

of the self are gained through interaction with the environment, ethnic and racial identity constitutes integral aspects of youth development. Cultural values afford the information necessary to interpret and proactively respond to environmental experiences and stereotypic messages concerning minority status. Developing a sense of efficacy is crucial during adolescence due to youths' heightened self-consciousness and greater cognitive awareness; however, this self-efficacy is partially determined by the opportunities, limitations, and expectations that society imposes on youth. Successful performance on a particular task increases a sense of personal empowerment (i.e., competence) and the likelihood of future successes in subsequent tasks.

Comprehensive, Developmentally and Contextually Sensitive Theory

The final corrective we propose is a contextually and developmentally sensitive theory that integrates all of these issues. We employ Spencer's (1995) PVEST as an overarching framework to accomplish this end. PVEST builds on multiple theoretical traditions in developmental psychology (e.g., Boykin, 1986; Bronfenbrenner, 1977) and other disciplines (e.g., Chestang, 1972b), including subfields of psychology (e.g., Steele, 1997); all address one or more of the issues noted earlier. As a dynamic and systemic framework, PVEST serves as a tool for examining resilience and vulnerability in conjunction with normative human development, focusing on identity formation while taking into account structural factors, cultural influences, and individual phenomenological experiences and perceptions of these contextualized features. In the next section, we present PVEST as the integration of several developmental traditions, including Erikson's and Marcia's theories of identity formation and symbolic interactionism and Bronfenbrenner's ecological systems theory.

BUILDING TOWARD A PHENOMENOLOGICAL VARIANT OF ECOLOGICAL SYSTEMS THEORY

Spencer's (1995) PVEST builds on a long tradition of theory in the realm of normative human development. The broad scope of this work spans several disciplines, covering ideas about individual developmental processes such as identity formation theories and racial identity theories, traditions such as symbolic interactionism that emphasize

the self in relation to society, particular concerns of applied youth development such as resilience theorizing, and contextually sensitive schools of thought such as the ecological psychology school. Each of these traditions highlights particular salient issues in normative human development. We review the major trends that influenced the model (Spencer, Harpalani, Fegley, Dell'Angelo, & Seaton, 2003) as a strategy to better understand these issues and to gain a more sensitive grasp on PVEST.

Theoretical Underpinnings of Identity Formation Processes

In considering resilience and vulnerability, it is critical to understand the developmental underpinnings of identity and self. In fact, we conceptualize resilience essentially as an identity: an achievement-oriented sense of self attained by the individual to overcome obstacles (risks) by drawing on available resources (protective factors). This process can be best understood within a theoretical framework that seeks to explain how youth effectively meet the demands of developmental tasks in infancy, childhood, and adolescence. Moreover, a child's ability to successfully navigate various life stages emerges in the context of social relationships embedded within the child's unique societal and cultural environment. Knowledge of self, knowledge of the world, and knowledge of how to regulate self in relation to other develop in these contexts. Once we build an understanding of identity and self processes from a normative human development perspective, we can apply this understanding to various contexts of differing levels of vulnerability, thus building toward a normative developmental view of resilience.

Identity in psychological theorizing is viewed as the core character of an individual that provides psychological stability across time and space. More recently, the concept of identity has been expanded to include a wide variety of domains of self; for example, there are growing literatures on racial, ethnic, gender, sexual, and national identity. We cover some of these later in conjunction with our discussion of race and ethnicity. Here, we draw on the classical theoretical frameworks of Erikson and Marcia and limit our discussion to what is commonly referred to as "ego identity."

One of Erikson's (1968) primary contributions was to define stage-specific concepts of development more explicitly. Prior to Erikson, stages of human development between life and death were not clearly formulated or articulated; the individual merely progressed from baby to

adult. Of course, there were limited exceptions, for example, Piaget's (1932, 1970) work on cognitive development, but often these involved a limited domain (e.g., cognitive reasoning) or limited stages (e.g., childhood). Stages of life course human development, along with the transitions between them, had not been discussed widely (Zelizer, 1994). In his epigenetic model, Erikson (1968) proposed that development occurred in stages across the life course in a fixed order: childhood, adolescence, adulthood, and old age. He identified eight stage-specific developmental tasks across the life course: trust versus mistrust, autonomy versus shame, industry versus inferiority, identity versus identity confusion, intimacy versus isolation, generativity versus stagnation, and integrity versus despair, and initiative versus guilt. The eight stages represent developmental challenges that must be negotiated and renegotiated throughout the life course.

Erikson's (1959, 1968) model highlights the centrality of identity in human development. In his theorizing, a large component of identity formation occurs during youth and particularly during the period of adolescence—the time marked by the active search for identity. Here, youth must grapple with the challenge, or “crisis,” of increased independence, sexual maturation, greater cognitive ability, pressure to conform to social norms, and heightened awareness of others' perceptions of them. Youth rely less on parents for guidance about self, and peer groups begin to play an increasingly important role in this regard. The search for identity is further complicated by the onset of secondary sex characteristics and desire for intimate relationships, all of which play a role in self-definition, particularly with regard to gender identity. In technological, industrialized societies, there are numerous options for managing these newfound capacities and resultant traits of self. The manner in which youth tend to adapt to these circumstances across time and space defines their identity.

Erikson (1968) is also well-known for his concept of identity *crisis*. Crisis refers to a period of emotional and mental stress that can lead to significant alterations in worldview in a limited time. For example, a crisis may lead to changes in group or peer associations, political beliefs, or engagement in risk-taking behaviors. On the surface, crisis may appear to have a negative connotation, but this is not necessarily the case. Erikson's notion of crisis as a state of internalized tension is also an opportunity to cope and grow. When youth are presented with challenges, they have an opportunity to respond to these challenges and to learn in the process—essentially, to display resilience. This is a part of normative human development.

Marcia builds on Erikson's work by elaborating on identity formation and creating a typology for identity development. Like Erikson, Marcia describes adolescence as the time for active engagement in the search for identity, and building on Erikson's notion of crisis, Marcia (1966, 1980) delineates the process of identity development in terms of four different identity statuses: diffusion, foreclosure, moratorium, and achievement. During the first stage, *diffusion*, youth have not encountered significant crisis. The individual is not committed strongly to any particular way of being or perspective on life. *Foreclosure* assumes an early commitment to a conventional standard of behavior. Foreclosed youth do not actively explore different possibilities for identity formation; they tend to follow the traditionally socialized standards of behavior and resultant trajectories. Conversely, *moratorium*, if it occurs, can be a time of exploration, when alternative possibilities are explored. Subsequent to moratorium is identity *achievement*, when the individual has encountered crises and emerged from them with a stronger sense of self or, in Marcia's terminology, “high identity commitment.” This is also tantamount to demonstrated resilience. Of course, identity achievement is not universal or final; individuals continue to encounter new crises through the life course—particularly in domains that are not foreclosed or achieved—and thus, given domain-specific challenges encountered, must demonstrate continued resilience in this regard.

Both Erikson's work and Marcia's expansion contribute to and lay the foundation for our general conceptualization of identity development. To examine issues of vulnerability for racially and ethnically diverse youth, it is useful to apply these concepts more specifically in the domains of race and ethnicity and consider racial and ethnic identity theories.

Theories of Racial and Ethnic Identity

Theories of racial and ethnic identity draw on Eriksonian and Marcian theorizing and apply their concepts of identity formation to racial and ethnic awareness. Racial identity development refers to the “process of defining for oneself the personal significance and social meaning of belonging to a particular racial group” (Tatum, 1997, p. 16). William E. Cross is one of the pioneers in the study of racial identity. Cross's original nigrescence model (Cross, 1971; Cross, Parham, & Helms, 1991) delineated four stages of racial identity formation for African Americans. During the *preencounter* status, Black individuals view the world from a White, Eurocentric frame of reference, consciously or unconsciously holding pro-White and anti-

Black attitudes. The second status, the *encounter* phase, involves an event or series of events that cause individuals to recognize that they cannot fully assimilate into White society. These may be tangible experiences of racism, crises in an Eriksonian sense, which facilitate exploration of racial identity. The third phase, *immersion-emersion*, is a consequent reaction to the encounter phase. Here, individuals become more interested in their Black identity and show increased awareness of racism and sensitivity to it. This phase may be characterized by anti-White attitudes. Individuals will also show a superficial immersion in realms associated with Black cultural attributes (e.g., music, speech styles). *Internalization* occurs as individuals become secure with their Black racial identities and move toward a more pluralistic perspective. African Americans then represent the primary reference group, but individuals' attitudes are not anti-White. In contrast to the superficial displays of the immersion-emersion stage, individuals in the internalization stage have more stable, deeply rooted connections to attributes of their Black heritage, and they may also have the ability to connect comfortably with aspects of White society; for example, they may have diverse groups of close friends. Consistent with this train of thought, Edgar Epps's (1985) analysis would suggest youths' adoption of a cultural pluralist perspective: the recognition and valuing of one's own group membership and cultural traditions along with an appreciation of ways of life associated with other groups.

Cross (1991) has modified the nigrescence framework as a more dynamic and flexible model of racial identity development. Individuals may recycle through the different stages at various developmental periods, and depending on parental racial socialization, they may not start in the preencounter stage. Thus, the stages should not always be viewed as a literal progression. Cross also added a fifth stage to the original four; this stage, known as *internalization-commitment*, represents a more consistent internalization phase. He has also described different modes of internalization, some of which include bicultural identities (W. E. Cross, personal communication, November 20, 2000). We would add that the preencounter stage should be further qualified when considered for young children. That is, given cognitive egocentrism manifest in the first 6 or 7 years of life, children's reported outgroup identifications represent a statement of their cultural early *exposure and experience* with particular cultural stereotypes rather than a conscious identification with or preference for Whites (Spencer, 1982a, 1983; Spencer & Markstrom-Adams, 1990). In other words, when considered from a

developmentally sensitive perspective, young children's stated and early identifications have more to do with what they are exposed to (e.g., unchallenged portrayals of racial stereotypes) than an internalized identification or an identity connoting a valuing of Whites and devaluing of Blacks. Unfortunately, for the most part, the absence of development-sensitive analyses continues to plague much of the racial identity literature.

Of course, White racial identity must also be studied to understand how race and ethnicity operate in development. Whiteness is usually not articulated, serving as the implicit norm, but scholars have begun to explore White racial identity. Most notable in this area is the work of Janet Helms (1990). Helms's model of White racial identity development consists of six statuses, organized in two developmental phases. The first phase, abandonment of racism, consists of three stages. *Contact*, the first stage, involves acceptance of the dominant status of White people, although not explicit awareness of this dominance or the subordinate status of people of color. *Disintegration* occurs as White individuals become aware of their dominant status in society and go through a period of dissonance. In *reintegration*, the person acknowledges his or her Whiteness and holds the view that he or she deserves the privileges accorded by this status. The second phase of Helms's model is called defining a nonracist White identity. This initiates with the *pseudo-independent* stage; individuals begin to question the dominant status of White Americans and may become overly involved with trying to help or change people of color. In the *immersion/emersion* stage, individuals begin to focus on changing White people rather than African Americans. With the final stage, *autonomy*, individuals achieve a positive racial identity and also appreciate and seek opportunities to learn from other groups.

Other theorists have built on this work and also examined ethnic identity. For example, Jean Phinney (1992) drew on Cross's (1971, 1991) racial identity theory and Marcia's (1966) work on identity statuses to devise the Multigroup Ethnic Identity Measure, a psychological assessment instrument that can be used across diverse groups. However, even if researchers acknowledge the significance of racial and ethnic identity, conceptual challenges remain. As noted earlier, academics may define race and ethnicity differently and precisely, but these constructs are inextricably linked in people's own meaning-making systems. It is important to be clear about the particular definition of race/ethnicity (or combination of the two) in use, and, of course, this depends on the context and issues that are being examined. For example, Chinese

Americans, Vietnamese Americans, and South Asian Americans may all be classified as Asian American even though there is significant within- and between-group variation in these categories. Their different histories and locations in American society are important to consider in the realm of ethnic identity development. However, at the same time, it is important to note that different groups such as Chinese, Vietnamese, and South Asian Americans may have similar racialized experiences; they may be identified by others as one racial group and thus stereotyped and stigmatized in a similar manner (i.e., the “model minority” myth; see Takaki, 1998). Thus, there may also be a dimension of similarity in their experiences, and depending on the issue and context of investigation, it may be more useful to emphasize the similarity or the difference of various experiences.

In that vein, identity and self should be placed in context to help distinguish salient developmental issues in particular situations. To build toward a PVEST, we must also consider the notion of self in relation to society, as the understanding of self processes is central to our developmental framework.

Self in Society

Identity and self not only develop within larger social contexts; they are also impacted by those contexts. William James (1892/1961) was a pioneer in describing the relational nature of the self. According to James, the self comprises two components: the “I” and the “Me.” The “I” includes the self-as-knower, the active observer, the subjective self, the observing ego, and the private self. “I” organizes and interprets the self’s experiences and reflects on the “Me.” Additionally, “I” is commonly alluded to as the self-conscious, self-reflective element of self.

In contrast, the “Me” is described as the self-as-known, the observed self, the objective self, the empirical self, or the public self. “Me” is the collection of perceptions regarding the self; these include tangible, material aspects of self (body, possessions, family), the social self (others’ views of the self, relations, roles, personality), and the spiritual self (inner psychological workings, including thoughts, wishes, desires). “Me” is commonly referred to as the self-concept component of self.

James’s (1892/1961) theory has significant implications for identity development. His work emphasized the reciprocal quality of the self, and with the advent of cognitive maturation, adolescents become increasingly aware of the duality of self (Broughton, 1981; Rosenberg, 1979). At this developmental period, youth begin to distinguish be-

tween their own public and private selves, a phenomenon that is central to the identity crisis and exploration associated with adolescence (Erikson, 1968; Marcia, 1966, 1980). As children’s social networks also expand at this age, they begin to see themselves in multiple roles, some of which demand very different ways of presenting oneself. Thus, cognitive dissonance is compounded. The central task of adolescence is the quest to integrate the various selves and achieve equilibrium with a stable sense of self (Hart, 1988). Failure to accomplish this can lead to fragmentation and to the impression that one’s self is merely an empty shell or façade, malleable to suit every person and situation. This can be problematic in various domains, as future developmental tasks ranging from goal-setting and accomplishment to the development of healthy, stable social relationships all require youth to have a strong sense of who they are.

All of these are normative developmental tasks that all youth must negotiate. But it is important to consider how these issues are compounded for youth of color. Cultural dissonance across school, family, and peer contexts can make the integration of self more difficult. Moreover, racial stereotypes also impact self-concept and may create dissonance about goals and preclude opportunities for exploration. These issues will be explored in greater detail in later sections of the chapter.

The symbolic interactionists, including Charles Horton Cooley and George Herbert Mead, made significant contributions to understanding the social nature of the self. Cooley (1902; Scheibe, 1985) is best known for his metaphor of the “looking-glass” self. According to Cooley, children participate in interpersonal networks, which yield perceptions of reflected appraisals from others. Through this participation and self-appraisal, they develop their own sense of self. It is not others’ attitudes that are critical in the formation of self, but rather the individual’s perception of other’s attitudes (i.e., an individual’s personal phenomenology; Rosenberg, 1979).

Mead (1934; Scheibe, 1985; Taylor, 1991) elaborated on Cooley’s notion of the looking-glass self. According to Mead, self-aware people see themselves through the eyes of others; consequently, they may act in ways to gain others’ approval. Contingent on the situation at hand, individuals may respond to others with varying presentations of self (Goffman, 1959). These presentations of self can elicit varying reactions, all of which have an impact on self-concept and identity formation. For youth of color, these issues are manifested in various ways, from the phenomena of code switching and “double consciousness” (Du Bois, 1903) to the misinterpretations of Fordham and

Ogbu (1986; see Spencer, Cross, Harpalani, & Goss, 2003, for a critique).

Building on the work of Cooley and Mead, Harry Stack Sullivan (1953; Epstein, 1973; Mitchell, 1988), describes how the self system evolves from significant external factors associated with one's cultural, social, and interpersonal experiences. The self system serves as a filter for and organizer of these experiences, influencing how the individual interprets and responds to others. Sullivan posits that the self system develops out of an endless loop of interactions between the individual and others; it is the product of these interpersonal situations and serves as the lens through which self and the social context are perceived and evaluated. Sullivan particularly emphasized the importance of reciprocal relationships between the child's interactions with the parents and significant others; in contrast, Mead focused on relationships with society at large (what he termed the "generalized other"). Of course, all of these levels of context are important in identity formation; they are elaborated in the next section.

Ecological Systems Theory

Bronfenbrenner's (1979, 1989, 1993) ecological systems theory provides an ideal framework to characterize levels of environmental influence that impact human development. These levels of influence are cast in terms of dynamic, interactive systems of person-environment relationships. Ecological systems theory is organized hierarchically, as interactive systems of increasing complexity are nested within the framework of human development. Bronfenbrenner (1979, 1993) starts by transforming Lewin's (1935) formulation that behavior is a function of person and environment; he substitutes development for behavior, stating that development is also a function of person and environment over time. The developmental function is temporally contingent, as each successive developmental period is dependent on all previous stages of development.

Several types of theoretical models characterize research in developmental psychology. According to Bronfenbrenner (1993), theoretical constructs in developmental psychology have usually focused only on characteristics of the individual, ignoring context. Developmental characteristics of individuals make no reference to the environments where they occur; examples of such constructs include standardized psychological measures such as personality and IQ tests. Bronfenbrenner (1989) refers to this type of analysis as the *personal attributes model*; it focuses narrowly on the individual, with the assumption that researchers can generalize conclusions derived from stan-

dardized measures, regardless of context. Bronfenbrenner (1993) questions these assumptions of environmental generalizability; he does note the utility of standardized tests but argues that research must simultaneously incorporate context-oriented measures.

The most common approach in developmental psychology, according to Bronfenbrenner (1989), is the *social address model*. In contrast to the personal attributes model, the social address model examines only general environmental factors, such as social class, family size, and other demographic variables. It tends to neglect specific environmental characteristics, along with activities that occur in particular environments, and the impact of these activities on individuals (Bronfenbrenner & Crouter, 1983). Essentially, the social address model employs the simplistic view of context critiqued by Van Oers (1998), which we noted earlier.

The *person-context model* examines both the individual and the context but neglects the processes involved in development. For example, this might include studies of personality or attitudes that control for specific environmental characteristics, such as parent-child interactions, without specifying how those characteristics are related to the outcome at hand. This person-context model is able to specify ecological niches (Bronfenbrenner, 1989), but it does not delineate the processes by which developmental outcomes are attained. A process-oriented approach is necessary for understanding resilience and vulnerability, which, as noted earlier, should be conceptualized in terms of processes rather than traits.

Conversely, Bronfenbrenner's (1979, 1989, 1993) ecological systems theory is a *process-person-context model*; it underscores the variability within developmental processes as a function of person and environment. Ecological systems theory (Figure 16.1) is organized with four hierarchically nested levels of environmental influence that mediate person-environment interaction: microsystem, mesosystem, exosystem, and macrosystem. The first level of Bronfenbrenner's model, the *microsystem*, involves the interaction of the person with the immediate social and physical environment; examples include home, family, and school settings. All higher levels of environmental influence are filtered through one or more microsystems, where the individual's actual experiences occur. *Proximal processes* are the patterns of person-environment interactions that occur within microsystems, and these change through the development of the person (Bronfenbrenner, 1979, 1989, 1993). Elsewhere, Bronfenbrenner and Ceci (1994) discuss how proximal processes mediate the heritability of traits by allowing individuals to actualize their potentials.

Figure 16.1 Bronfenbrenner's Ecological Systems theory. Sources: From *The Ecology of Human Development: Experiments by Nature and Design*, by U. Bronfenbrenner, 1979, Cambridge, MA: Harvard University Press; "Ecological Systems Theory" (pp. 187–248), by U. Bronfenbrenner, in R. Vasta (Ed.), *Annals of Child Development*, 1989, Greenwich, CT: JAI; and "The Ecology of Cognitive Development" (pp. 3–44), by U. Bronfenbrenner, in R. H. Wozniak & K. W. Fischer (Eds.), *Development in Context: Acting and Thinking in Specific Environments*, 1993, Hillsdale, NJ: Erlbaum.

The *mesosystem* is the second level in Bronfenbrenner's (1979, 1989, 1993) ecological systems theory; it describes interactions between the various microsystems in the individual's life. Mesosystems essentially constitute networks of interpersonal relationships that span the various settings. The third level, the *exosystem*, entails more distal influences, such as the structure of the community where the individual resides and settings where the individual is not directly present. For example, interactions at a parent's work setting would constitute exosystemic influences; these do not directly involve the child but may impact his or her development.

The final level, the *macrosystem*, consists of larger societal institutions, such as government, economy, and the media, that lay the broad social and historical context for development (Bronfenbrenner, 1979, 1989, 1993). The impact of macrosystem-level influences may or may not be readily apparent in the lives of individuals, but it is always present in salient ways. The overarching patterns of social practices and relationships found through micro-, meso-, and exosystems often result from macrosystemic factors. Typically, sociologists, political scientists, and economists, rather than developmental psychologists, have studied macrosystems. Nevertheless, developmentalists must also be attuned to the

subtle but explicit ways in which larger societal forces filter through multiple layers of context and influence life trajectories and outcomes. Without attention to this caution, particularly as applied to the experiences of youth of color, the frequent interpretation of "gap outcomes" (e.g., health and achievement disparities) blames performance differences on those experiencing significant risks; further, the risks are often characterized as not representing multiple levels of environmental differences but, instead, are interpreted as deficits and pathologies of the individuals themselves.

Ecological systems theory provides a conceptual foundation for examining the multiple layers of context that influence human development as well as the interactions between these layers. Nevertheless, our aim is to link this comprehensive view of contextual influence with concepts from identity theory and symbolic interactionism, all in an effort to conceptualize how the individual is living in context. Bronfenbrenner's (1989) model provides a means for describing multiple levels of context; Spencer's (1995) PVEST combines a phenomenological perspective with Bronfenbrenner's ecological systems theory, linking context and perception. In contrast to Bronfenbrenner's focus on levels of context (e.g., microsystem, mesosystem) PVEST directly illustrates life course human development *within* context. Additionally, in their provisional role as sources of either risks or protective factors transformed as experiences of challenges or supports, the other levels of the ecological context are also integrated as lives unfold across the life course. A consideration of the combination of influences allows us to describe the components and processes of development. Accordingly, we employ PVEST to analyze the meaning-making processes that underlie identity development and outcomes that transpire as individuals transition across contexts (Spencer, 1995, 1999; Spencer, Dupree, & Hartmann, 1997). In the next section, we synthesize our building blocks to describe Spencer's (1995, in press) PVEST.

PHENOMENOLOGICAL VARIANT OF ECOLOGICAL SYSTEMS THEORY: AN IDENTITY-FOCUSED, CULTURAL-ECOLOGICAL PERSPECTIVE

The PVEST serves as a model to examine normative human development framed through the interaction of identity, culture, and experience as linked with progressively differentiated maturational processes. PVEST utilizes an *identity-focused cultural-ecological* perspective, integrating issues of social, historical, and cultural context with normative developmental processes. The model aims to capture

the individual's intersubjectivity and meaning-making processes in light of tangible experiences, which are determined by the proximal and distal contexts of development. PVEST centers on describing individual identity formation unfolding over time. Although both ecological systems theory and PVEST, its phenomenological variant, account for identity formation and context, we believe our focus on direct description of identity formation in a life course framework allows for a more comprehensive explanation of human development. As noted by Cooley (1902), Mead (1934), and Sullivan (1953), the self is mediated by interpersonal relationships, influenced by the phenomenological experience of multilayered, contextual influences and relationships (Spencer et al., 1997). It is the combination of experiencing micro- and macrocontextual influences, normative develop-

mental processes, salient interpersonal relationships, and the cognition-based perceptions and phenomenological experiences that delineate identity formation and eventually yield resilient or adverse outcomes. Determining how we view and comprehend family, peer, and societal expectations, as well as their prospects for competence and success, is central to understanding resilience and devising interventions that promote it (Spencer, Harpalani, Fegley, Dell'Angelo, & Seaton, 2003). Moreover, for youth of color, it is important to understand how broader societal inequities and biases influence these processes.

Considered from this nonstatic perspective, PVEST is a systems theory consisting of five basic components linked with bidirectional processes that form a dynamic developmental framework (see Figure 16.2); it is a cyclic, recursive

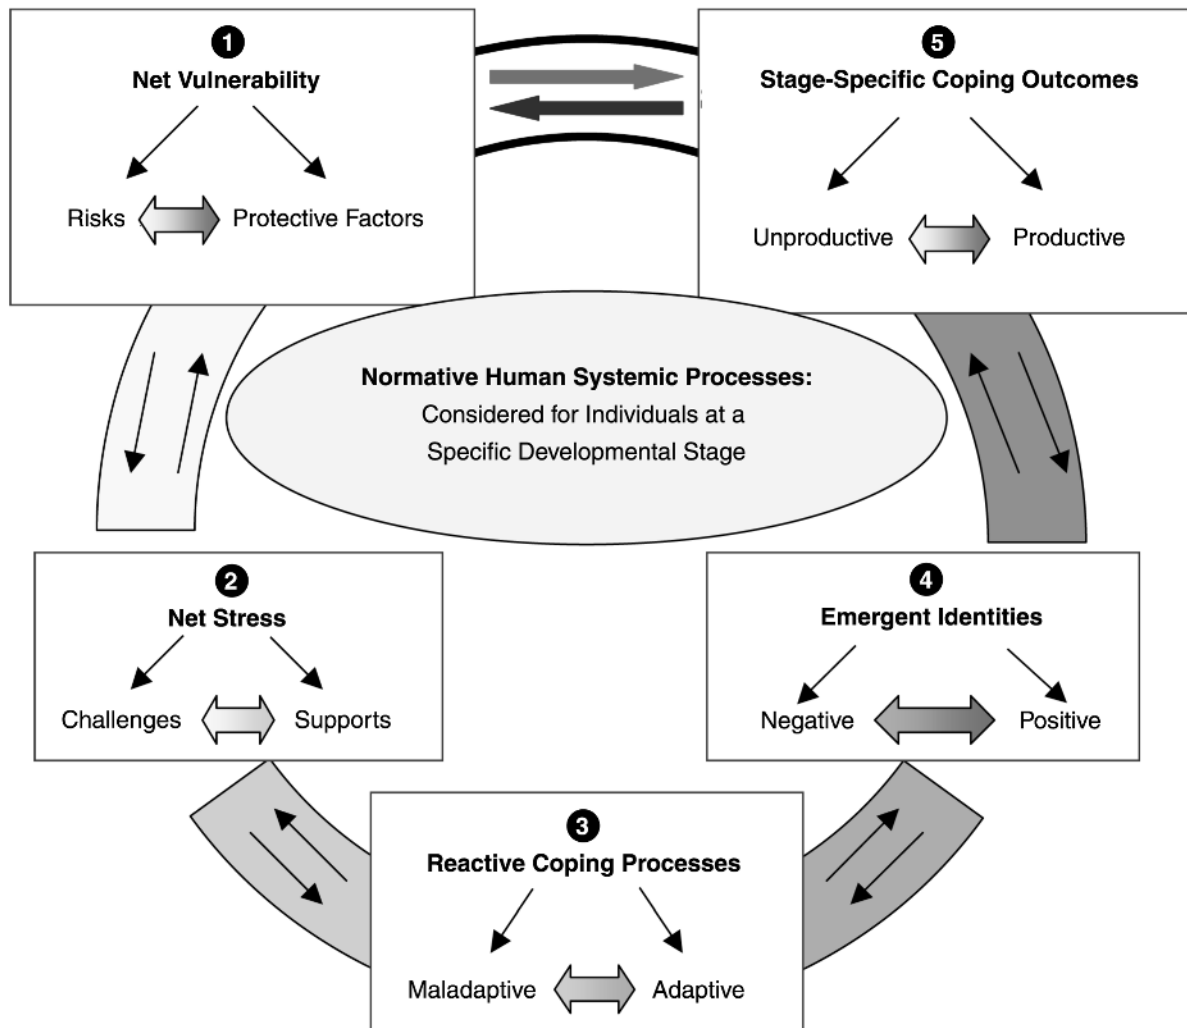

Figure 16.2 Phenomenological Variant of Ecological Systems Theory (PVEST). *Source:* From “Old Issues and New Theorizing about African American Youth: A Phenomenological Variant of Ecological Systems Theory” (pp. 37–70), by M. B. Spencer, in R. L. Taylor (Ed.), *Black Youth: Perspectives on Their Status in the United States*, 1995, Westport, CT: Praeger.

model that describes identity development throughout the life course. Our approach affords a better understanding concerning not just the “what” but, more important, the “how” of development (see Spencer & Harpalani, 2004).

The first component of PVEST, *net vulnerability*, level (1), consists of the contextual and personal characteristics that may potentially pose challenges during an individual’s development. Risk contributors are factors that may predispose individuals for adverse outcomes. These may be offset by protective factors, thus defining net vulnerability for a given individual. For marginalized youth, such as youth of color and young people from low-resource families, these include socioeconomic conditions such as living in poverty, imposed expectations such as race and gender stereotypes, and the influences of larger historical processes such as racial subordination and discrimination. Perceptions of the risks one faces and the protective resources available are central to the process of identity formation. Self-appraisal involves constant close scrutiny and evaluation of these risks and resources; the process is particularly salient for identity formation during adolescence, when cognitive and emotional maturation lead to heightened awareness of self and context.

Net stress engagement (2), the second component of PVEST, refers to the actual experience of situations that challenge an individual’s well-being. Available social supports can help youth negotiate experiences of stress; thus, supports are actualized protective factors. Whereas risks and protective factors denote potential entities in the environment, stress and support refer to actual manifestations of these entities—experiences in context, as it were. In this way, PVEST forges a link between context and experience. For youth of color, experiences of racism, both subtle and overt, and related dissonance are salient and often chronic stressors; these compound the normative developmental issues encountered by all youth (e.g., puberty, identity exploration, peer relationships). As noted, cognitive maturation results in unavoidable awareness of dissonance, and in adolescence, acute reactions to these experiences are coupled with normative rebellious behavior; thus, this is a period when risk is escalated. Adult role models and other resources in school, family, and community settings can serve as social supports and help youth cope with these experiences.

It is important to note that although stress engagement poses challenges, the construct of stress in PVEST is not entirely negative. It is derived from, and in many ways similar to, Erikson’s view of crisis. As we discuss later, stress not only poses challenges but also provides opportunities to develop and hone coping skills.

In response to stressors and in conjunction with supports, *reactive coping methods* (3) are employed to resolve dissonance-producing situations. Reactive coping responses include problem-solving strategies that can lead to either adaptive or maladaptive solutions. Interpreting experiences and determining how to respond to them involves the development of patterns of coping, which are both immediate and long term. All youth must learn to cope with different sources of stress as part of normative human development; but as noted, these issues are compounded for marginalized groups. Additionally, it is important to recognize that a given coping strategy may be adaptive in one context (such as school) and maladaptive in another (e.g., neighborhood; H. C. Stevenson, 1997). Moreover, such dissonance accrued and linked to the deployment of coping strategies is more likely to occur for youth of color (Phelan, Davidson, & Cao, 1991).

Over time, coping processes shape an individual’s sense of identity. As youth employ various coping strategies, self-appraisal continues, and individuals replicate those strategies that produce desirable results for the ego. These become stable coping responses that, coupled together, yield *emergent identities* (4). Emergent identities define how individuals view themselves within and between various contexts of development (e.g., family, school, and neighborhood). The combination of cultural/ethnic identity, sex role understanding, and self- and peer appraisal all produce one’s identity at any given time; these domains and the interactions between them are also constantly changing, evolving, and thus defining the process of identity formation.

Identity processes afford behavioral stability over time and space; as such, they provide the foundation for future perception, self-appraisal, and behavior. This leads to either adverse or productive *life-stage-specific coping outcomes* (5), the final component of PVEST. Productive outcomes include good health, educational attainment, positive relationships with others, and high self-esteem; on the other hand, adverse outcomes include poor health, incarceration, and self-destructive behaviors. Resilience is the attainment of productive outcomes in spite of adverse conditions (i.e., disproportional to expectations risk level experienced as significant challenge).

PVEST is a cyclic framework that represents dynamic, developmental processes that continue throughout the life span and aids in explaining the “how” of developmental processes. It aids in explaining the frequent diversity obtained for specific life-stage coping outcomes by demonstrating the undergirding mechanisms by which individuals (1) balance new risks against protective factors;

(2) encounter new stressors (i.e., challenges potentially offset by supports); (3) establish new coping strategies (i.e., manifested reactively “in the moment” as either adaptive or maladaptive responsive efforts); and (4) redefine how they view themselves, which also impacts how others view them. PVEST provides a normative human development framework to examine the range of outcomes, including resilience, for all youth. It highlights the importance of development in context, with identity formation at the core. Moreover, it is important to recognize that the five components of PVEST are merely stopping points for analysis; it is the processes that link these components that actually constitute normative human development. PVEST allows us to conceptualize how the normative processes of development are exacerbated for marginalized youth, and how resilience and vulnerability are manifested as part of the context-linked processes of normal human development. Although recent scholarship has thoroughly reviewed literature on youth of color (e.g., Fisher et al., 1998) and provided contextually sensitive models to examine developmental competencies among these youth (Garcia-Coll et al., 1996), it is the direct, process-oriented delineation of developmental trajectories throughout the life span that makes PVEST unique.

VULNERABILITY AMONG RACIALLY AND ETHNICALLY DIVERSE YOUTH: A GENERAL OVERVIEW

Having presented PVEST as a comprehensive, dynamic, normative developmental framework, we now apply this framework to examine vulnerability and resilience among racially and ethnically diverse youth. Although much of our focus here is on the first component of PVEST, net vulnerability level, we consider all five components, along with the developmental processes that link them.

The broad, contextual factors that exacerbate normative developmental challenges for youth of color are vast and numerous; many books have been written about each of these issues. We focus on some illustrative examples highlighting various groups. First, we briefly cover structural and ideological manifestations of racism and then explore one of these, skin color bias and attitudes, in more detail. We then turn our attention to the context of immigration in the United States and explore issues such as cultural dissonance and dual identification that render the task of identity formation more difficult for immigrant youth. These topics are covered as representative of normative undertak-

ings confronted by youth of color, but they are by no means a complete account of these challenges.

Structural and Ideological Legacies of American Racism

Race and racism have been perhaps the most charged political issues in U.S. history. Various historical and political forces brought about the current racial/ethnic composition and demographic trajectory of the United States, and these forces serve as the broader social and historical context for the everyday experiences of all Americans. Traditional definitions of racism view it simply as discrimination based on race; these neglect the innumerable ways the phenomenon of racism impacts lives. Racism is omnipresent, though often subtle; it is channeled through multiple levels of context, as described by Bronfenbrenner (1979). It is inclusive not only of discriminatory behavior, but also of structural power relationships, political ideologies, and institutionalized practices, all of which can be normative, albeit unacknowledged, components of society. There are various and salient ways racism impacts lives, not only by disadvantaging people of color but also by privileging White people.

Omi and Winant's (1994) *racial formation* perspective is among the most widely cited sociological theories of racism, and it presents an ideal framework to describe the formation of racial ideologies, which are also expressed in everyday life through stereotypes, assumptions, and other forms of tangible bias. Omi and Winant define racial formation as “the sociohistorical process by which racial categories are created, inhabited, transformed, and destroyed” (p. 55). Racial formation focuses on the process of racialization and recognizes the multiple levels at which racism occurs, with macrolevel structural manifestations translating into individual everyday experiences at the microlevel. “Racial projects,” according to Omi and Winant, are historically situated interpretations and explanations of the racial relationships in a society; these serve to reallocate resources across racial groups and can serve as explanations/justifications for inequities. Other perspectives, such as that of Bonilla-Silva (2001), have built on Omi and Winant's work and emphasized structural and ideological dimensions of racism.

Structural Racism and Economic Inequities

Structural factors center on the social relationships inherent in racial inequity. For example, poverty is a major structural barrier to success for African American youth. Moreover,

the racialized nature of poverty goes beyond monetary income; community resources and accumulated wealth also play a critical role. For example, Sampson and Morenoff (1997) reported that in 1980, 85% of poor Black Americans lived in impoverished areas lacking in community resources; only about 30% of poor White Americans lived in such areas. More than 33% of poor African Americans resided in extremely impoverished neighborhoods, as compared to only 7% of poor White Americans. The impoverished communities where poor African Americans often reside are characterized by different family structures, few economic opportunities, few recreational facilities, poor quality of schooling, and lack of available role models.

Similarly, Conley (1999) notes the critical distinction between income and wealth. Even when controlling for income, White Americans tend to have much greater net worth than Black Americans when measuring total assets. This disparity is due partly to differences in home ownership, which have a historical basis in redlining and restrictive covenants, issues that are all the more salient because housing discrimination laws are so weakly enforced. Income has a large impact on many areas, including the ability of Black families to afford higher education. Thus, the history and ecology of poverty and wealth distribution reflect the legacy of structural racism inherent in American society. In the context of these continuing structural barriers, Black youth have limited access to resources and limited opportunities to visualize and comprehend success and attainment. In the absence of resources, successful role models, and social supports, experiences of dissonance and normative developmental challenges can yield negative outcomes such as academic underachievement.

Other sources of vulnerability and potential stress, resulting from poverty and related ecological risks, exacerbate normative developmental challenges when experienced by many African American youth. Growing up in poverty has been related to higher teen pregnancy rates among Black youth (Mayer & Jencks, 1989). More than 50% of African American children are born to unwed teen mothers, with poor nutrition and medical care often characterizing the prenatal period (Spurlock & Norris, 1991). The noted economic conditions are not independent of associated challenges that leave Black men unemployed or underemployed (see M. L. Sullivan, 1989); accordingly, some men may be viewed as less than optimal options for stable marital relationships. The consequences have implications for the character of the surroundings in which children's growth and development take place. Adverse neighborhood conditions, which are not independent of the economic circumstances described, can lead to developmental deficiencies early in

life; for example, anemia, lead poisoning, and ear infections often afflict urban African American and Latino preschool children and, considered long term, have implications for learning and mental health. Of particular importance, they influence the possibility of either high vulnerability or manifested resiliency. Although family and home characteristics vary substantially at all income levels, children growing up in low-economic-resource families and highly impoverished areas are more likely to experience stressors such as an unstable home life, parental neglect, and violence (Tuakli-Williams & Carillo, 1995). Without proper supports, these can lead to impaired cognitive and social development, with consequences such as deficient language acquisition, social withdrawal, and depression. It is the pattern of psychosocial and health-related stressors coupled with low societal expectations that can lead to poor academic achievement and high-risk behavior if proper supports are not provided. For example, appropriately designed and supported interventions can create more stable family structures, effective parenting skills, and conflict-resolution supports.

As indicated, it is also important to note that even in the most adverse circumstances, many families already draw on such resources, and consequently, children are able to attain resilient outcomes in spite of the exacerbated challenges they confront (see Swanson, Spencer, Dell'Angelo, Harpalani, & Spencer, 2002). Vulnerability means that risks are present, but actual experiences of stress can be avoided if adequate protective factors are present or youth can draw on resources to negotiate this stress effectively.

Vulnerability Related to Violence

Violence is another source of vulnerability for urban youth, particularly in terms of victimization. Shakoor and Chalmers (1991) found that approximately 75% of African American youth surveyed in Chicago schools had been "covictimized," witnessing directly the perpetration of serious violence (e.g., shooting, stabbing) against another person. Covictimization may lead to Posttraumatic Stress Disorder, and such exposure to violence has also been linked to the perpetration of violence (DuRant, Cadenhead, & Pendergrast, 1994). Adolescent and young adult Black males have disproportionately high rates of victimization (Donziger, 1996). Moreover, Cunningham (1999) found that Black males are keenly aware of danger, and that cognitive appraisals of risk were significantly strong predictors of hypermasculine coping (i.e., beliefs that violence is manly). May (2001) also found that Black males were significantly more fearful of victimization than their White counterparts and resorted to carrying more lethal defensive

weapons. H. C. Stevenson (1997) reports that many Black youth reside in high-risk neighborhoods where displays of anger may be necessary and represent adaptive coping mechanisms to avoid victimization; indeed, display of anger may be a form of competence for social and emotional viability in these contexts. Also, hypermasculine posturing necessary to avoid victimization may also mitigate school adjustment (Spencer, 1999) by means such as reinforcing negative teacher perceptions. Moreover, these kinds of phenomena must be understood in light of the salient, existing negative stereotypes of Black males, which are already rooted in hypermasculine imagery (Ferguson, 2001).

In sum, violence poses a complex series of threats to resilience for Black males. First, violence and victimization are maladaptive, leading to obvious adverse outcomes. Second, African American males are often perceived by society to be especially hostile, and as a consequence, they are treated unjustly by law enforcement and social agencies. Whereas White youth with psychological adjustment problems are often referred to mental health (and often private) services, African Americans are usually placed in the criminal justice system for the same offenses (Spurlock & Norris, 1991). The differences in treatment options available or system type used (i.e., private vs. public), although generally not acknowledged, have implications for the accumulation of statistics in the public domain and their contributions to and reinforcement of negative imagery and stigma. Third, as H. C. Stevenson (1997) describes it, displays of aggression by some Black youth may be adaptive responses in high-risk neighborhoods, where anger displays may be necessary to mitigate victimization. The conundrum, of course, is that such displays, in conjunction with negative stereotypes of African American males, may be misunderstood in school settings, where they constitute maladaptive coping responses. Thus, dissonance across the various settings of development may compound the issue, because violence functions as a complex, multifaceted source of vulnerability for African American youth (Spencer, Dupree, Cunningham, Harpalani, & Munoz-Miller, 2003; Spencer, Fegley, Seaton, & Harpalani, in press).

Racial Stereotyping

A related and significant source of vulnerability for youth of color is racial stereotyping, in all of its manifestations. Awareness of racial stereotypes and group membership status plays a key role in identity formation, particularly in adolescence, as identity and appraisal by self and others become prominent developmental issues. In addition to the negative stereotyping noted earlier with regard to aggres-

sion and violence, racial stereotypes present a barrier to academic achievement and resilience for African American youth. Claude Steele's (1997, 2004; Steele & Aronson, 1995) work on *stereotype threat* highlights these issues. Stereotype threat is essentially the fear of confirming a negative stereotype in circumstances where that stereotype is primed and salient; Steele and colleagues have experimentally demonstrated how stereotypes can negatively impact the academic performance of Black college students. Although their work has emphasized the experiences of college students, we infer that the mechanisms are also relevant for adolescents. Moreover, the phenomenon of stereotype threat is most salient for high-achieving Black youth (i.e., those demonstrating resilience "to date"), who have a great desire and expectation to succeed.

Academic stereotypes can also be a source of vulnerability for Asian American youth, who are often monolithically viewed as high-achieving "model minorities." This can create tremendous pressure to succeed and meet expectations. Even seemingly positive racial stereotypes have a negative side; Asian American youth are often taunted as "geeks" and "nerds," and they are viewed as passive and socially inept. Asian American males are stereotyped as weak and unmasculine, and females are portrayed as submissive. These stereotypes, in conjunction with other factors, can render these youth particularly vulnerable to mental health and social adjustment problems.

Stereotypes can be coupled in ways that complicate their impact and thus require more measured and thoughtful attention. To illustrate, positive and negative stereotypes can be coupled together, as is the case with African American athletes (Harpalani, 2001; Stone, Perry, & Darley, 1997). Here, the idea of African Americans as outstanding athletes, a seemingly positive attribute, is linked to the notion that African Americans are less intelligent and inherently lower achievers, due to genetic (Rushton, 1995) or cultural (Hoberman, 1997) factors. With regard to academic racial stereotyping, another subtle facet of vulnerability is lenient feedback and generally low expectations communicated from teachers; again, this becomes a risk factor as normative human development progresses. Cognitive maturation renders adolescents more sensitive and aware of implicitly communicated attitudes, beliefs, and explicitly conveyed feedback from elders and peers; additionally, they are more perceptive of false or deceptive tactics than younger children, who represent a less sophisticated level of social cognition. Harber (1998) illustrates that Black American college students in late adolescence and young adulthood may be so wary of praise from White Americans that receiving it may, in reality, depress their self-esteem. This is

another example of how a seemingly positive action can have negative consequences; intended support, in fact, may not be perceived in ways that are indeed supportive.

Given all of these factors, it is apparent that racial stereotyping is often more complex than stigmatization of mental illness and other devalued statuses. Corrigan and Penn's (1999) distinction between stereotyping (value-neutral cognitive categorization) and stigma ("negative" forms of stereotyping) may obscure salient issues in racial stereotyping. As illustrated, racial stereotypes that appear neutral or positive on the surface can reinforce other, negative stereotypes about respective groups. We've focused on minority youth; however, White adolescents have challenges that emanate from other issues and status concerns.

White Privilege

White privilege is a critical, although often ignored, element of any discussion of race and racism. Whiteness should not be normalized, and the history of White Americans as a racial group in the United States must be understood to explain the current privileges and challenges of White youth. The new field of Whiteness studies is particularly illuminating (e.g., Lipsitz, 1998), although the connections to normative human development have yet to be made in substantive ways. Nevertheless, Haney-Lopez (1996) and Harris (1993) provide compelling legal and historical discussions regarding the centrality of White as a legal category to the very definition of U.S. citizenship. Although formally legalized racial barriers to citizenship have been eliminated, the legacy of White supremacy continues in many ways and filters through multiple levels of context to impact everyday life.

For example, in her widely cited article, "White Privilege: Unpacking the Invisible Knapsack," Peggy McIntosh (1989, p. 10) defines White privilege as a "package of unearned assets which [Whites] can count on cashing in every day . . . an invisible weightless knapsack of special provisions." In this vein, White privilege basically encompasses the advantages that White people secure on the basis of skin color. In many instances, White Americans themselves are not generally aware of these advantages; the lack of consciousness itself may be due to the fact that advantages accrued represent incidents that do not take place, such as not being stopped unjustly by the police, not being followed in a store or suspected as a thief, not being represented in the news media primarily in negative ways (or ignored totally), and not being questioned about one's national loyalty, an even more salient issue in the post-

September 11, 2001, era. Because these are incidents that Caucasians do not generally experience, many fail to acknowledge or do not understand the everyday burdens that people of color encounter, or they tend to minimize the salience of these burdens. White Americans often take their own advantages for granted and attribute them solely to hard work and merit. Through the mechanism of intergenerational transmitted wealth (see Darity & Myers, 1998) and contemporary privileges (see M. L. Sullivan, 1989), White Americans have always had greater access to money, property, social and employment networks, and education than people of color. Moreover, the social and cultural practices of schools and workplaces are defined by White American norms, and cultural expressions by people of color, ranging from hair and clothing styles to language, are either discouraged in these settings, or they are embraced superficially under the rubric of "diversity," without a deep exploration of their meaning and significance. All of these factors contribute to the continuation of White privilege as a salient issue.

Another concept of importance needs to be introduced here: the *downside of privilege*. In the context of Whiteness, privilege is typically viewed as a racially dependent advantage, usually unfair in some broad sense. On the surface, privilege appears to serve as a protective factor, offsetting potential risks that more marginalized individuals may face. However, we can also view a privileged person as one who is not subject to particular experiences of stress engagement, for example, negotiating cultural dissonance or racial stereotyping. Youth of color who must negotiate these challenges have the opportunity to demonstrate resilience: successful coping with the given challenges. In the process, these resilient youth acquire and hone valuable coping skills, whereas privileged youth do not acquire these skills. Employing a PVEST cyclic perspective, youth who do not need to acquire these skills during one developmental cycle may need them at a subsequent time. The lack of requisite coping skills, due to minimal or nonengagement with stress, thus negates or undermines the possibility of resilience. This may lead to adverse outcomes in the future. As indicated, privilege, in fact, precludes the opportunity to hone coping repertoires, which may be necessary for later life challenges. In short, successful resolution of challenges makes youth more resilient, and those who do not encounter those challenges cannot be characterized as resilient because they remain untested outside of the normative encumbrances generally associated with a particular stage of development. Accordingly, being untested and having underdeveloped reactive coping skills enhances

their vulnerability. As a consequence, given the function of coping processes both for adequate responses in the moment (i.e., reactive coping strategies) and their patterned character as multiple emergent identities, one should consider the lack of coping skill actualization as the downside of privilege.

Although infrequently described as such, the 1999 student massacre at Columbine High School in Littleton, Colorado, and related incidents, along with the recent White identity theorizing (e.g., Helms, 1990) and general Whiteness discourse, support that there is a downside of privilege. As suggested, due to a lack of coping skill honing and actualization, privileged individuals become more dependent on the built-in and unacknowledged advantages enjoyed rather than developing their own abilities and authentic emergent identities. Much more research is necessary to determine the precise effects of privilege in different contexts. Recent research by Luthar (Luthar & Becker, 2002) and her colleagues provides credibility to this analysis. Of course, privilege is not just limited to race; other statuses such as gender, social class, ethnic/cultural background, skin tone, physical attractiveness, and sexual orientation can also confer privilege. Nonetheless, Kenneth B. Clark (1939, 1940) portended the downside of racial privilege 50 years ago with his expert testimony in *Brown v. Board of Education*. His report included evidence of “racial paranoia” and “unrealistic view of self” that segregation created among White Americans (see Harpalani, 2004). Consistent with the pathological ethos regarding African Americans, the U.S. Supreme Court ignored this evidence in favor of the Clarks’ doll studies, which have since been reinterpreted (Spencer, 1982a, 1983, 1984), as will be discussed later.

Multiracial/Biracial Identification

Individuals from biracial and multiracial backgrounds face challenges not only of marginalization as individuals, but also of dissonance of group identification. Historically, terms typically used to classify multiracial persons, such as “mongrel,” “half-caste,” “half breed,” “mulatto,” and “hybrid,” denote this lack of fit with the dominant realm of American racial categorization. Despite these distinct labels, societal attitudes have also typically asserted that a person with “one drop of [non-White] blood” is by default a member of the non-White group—another historic marker of White privilege.

Theorizing on biracial and multiracial identity development paralleled the deficit-oriented perspectives that char-

acterized previous scholarship on all youth of color. In this case, the dominant view was that biracial individuals face developmental problems because they are caught between two irreconcilable cultural contexts (H. W. Stevenson & Stewart, 1958). Stonequist’s (1937) *The Marginal Man* was one of the first proponents of this theory, stating that the biracial individual experiences personally the racial tensions of the society and is therefore alienated from both subcultures. In contrast, Kerwin, Ponterotto, Jackson, and Harris (1993) found that in their study, biracial adolescents did not perceive themselves to be marginalized as such. Much of the current debate still relies heavily on a marginal view of the multiracial individual’s development. An important future scholarly endeavor is to determine how the normative challenges of identity formation are exacerbated for biracial and multiracial youth without assuming pathology in the youth themselves. The question of multiracial identification is also highly politicized, with direct implications for U.S. Census categorization and resource allocation (Hernandez, 1998).

W. S. Carlos Poston (1990) and Maria Root (1990) have developed identity development models to address these issues unique to the multiracial population. Specifically, Poston draws on the concepts of personal identity and interpersonal competence with respect to reference group orientation. Similar to those of Cross (1971) and Erikson (1963), Poston’s model has a life span focus. His framework consists of five basic stages: personal identity, choice of group categorization, enmeshment/denial, appreciation, and integration. As the biracial individual moves through this process, according to Poston, he or she must examine and reexamine his or her own reference group orientation (again, reminiscent of Cross’s recycling process). Particularly in the third stage (enmeshment/denial), the biracial individual feels guilt and self-hatred surrounding his or her own reference group choice. Poston asserts, “When a multiethnic child is unable to identify with both parents, the child has feelings of disloyalty and massive guilt over rejection of one parent” (p. 154). The desired final stage of integration has been reached when the individual has been able to recognize and value all of his or her ethnic identities and feels a sense of wholeness.

Root’s (1990) model also acknowledges the guilt and self-hatred noted in Poston’s (1990) third stage. However, rather than accepting this stage as a necessary step for biracial development, she suggests an alternative route. According to Root, “For the biracial individual to reject either part of their racial heritage continues an internalized oppression” (p. 193). Also in contrast to Poston’s model, Root

does not identify a single healthy outcome. Rather, she maintains that there are four distinct possible healthy outcomes for the biracial individual: acceptance of the identity society assigns (similar to Marcia's foreclosure stage), identification with a single racial group (typically the minority group), identification with both racial groups (similar to Poston's integration stage), and, finally, identification as a new racial group. Of course, it is important to understand all of these possibilities in the larger context of racialization, with ever-changing racial categories and ideologies (Omi & Winant, 1994). Additionally, although generally not emphasized, parents' very early cultural socialization efforts (or lack thereof) matter and have important implications for youths' healthy identity resolution and reference group orientation (see Spencer, 1990).

Additional Sources of Vulnerability Due to Racial and Ethnic Marginalization

Numerous other sources of vulnerability are related to racial and ethnic marginalization in the United States. For example, the history of Native Americans in the United States, consisting largely of cultural and physical genocide (Churchill, 1994), has immense consequences for the development of indigenous youth. One of the monumental challenges to resilience of these youth is the need for more culturally sensitive basic research efforts.

Scores of other issues abound; however, owing to limited space and constraints due to expertise, we cannot cover them all. Instead, we supplement our general look at vulnerability among racially and ethnically diverse youth with an in-depth consideration of two issues of particular prominence across racial and ethnic groups: skin color bias and cultural dissonance. Although both of these issues affect the entire spectrum of people of color, we focus largely on African American youth for the former issue and immigrant and second-generation youth for the latter. In the process, we also illustrate in more detail the components of PVEST as unique analytic tools for examining vulnerability within normative human development.

VULNERABILITY AMONG RACIALLY AND ETHNICALLY DIVERSE YOUTH: COLORISM/SKIN COLOR BIAS

To understand how skin color bias can be a risk factor for youth of color (most significantly, Black youth), it is helpful to consider the historical context of race and color

stratification. Skin color is probably the most visible and salient phenotypic feature associated with racial categorization and related biases. Colorism, systemic bias, and inequity on the basis of skin color (usually privileging lighter skin tones over darker ones), even predates the notion of race in many societies. John Hope Franklin's (1968) volume *Color and Race* illustrated that colorism has existed in a number of areas around the world, including Japan (Wagatsuma, 1968), Northern Africa (J. S. Brown & Farber, 1968), South Africa (Legum, 1968), and India (Beteille, 1969). In parts of South and Central America, there is a correlation between darker skin tones and socioeconomic and political disadvantages. Issues of color hierarchy are prevalent in countries such as Brazil, where Portuguese invaders established a social system in which lighter-skinned Portuguese were on top, indigenous peoples were in the middle, and Africans were at the bottom (Russell, Wilson, & Hall, 1992). Even as many current Brazilians can claim mixed heritage, skin color still serves as a marker of social status. Other countries, such as Mexico, show similar color hierarchies.

In all of these societies, lighter skin tones are valued over darker skin tones, and color has broad implications for social status. Nevertheless, it is important to note that skin tone has taken on a particular structural significance in the United States. For example, on the surface, the social stratification and organization of the Indian subcontinent, based largely on the caste system, seems similar to the racial subordination inherent in the United States, with the two appearing as parallel hierarchies based on skin tone. However, the caste system of South Asia and the racial stratification of the United States differ in both origin and structure. Although skin color bias is apparent on the Indian subcontinent and perhaps even related to caste, skin color was not a key component in the creation of the caste system. Originally, European translators mistakenly assumed that skin color was the basis for caste divisions; this occurred because the Sanskrit term for caste, *varna*, translates as "color" (Koshy, 1998; Prashad, 2000). As noted by Koshy, there are classical Vedic references to upper-caste individuals with dark skin. Occupational delineation, rather than skin color, was the key component in the formation of the caste system.

In contrast, as Franklin and Moss (1994) note, the identifiability of Africans based on skin color was a key feature in the institution of slavery. Slavery in the Western Hemisphere became a massive economic enterprise. Slaves were systematically captured and bred for profit, creating a system of racial exploitation and segregation. This stood

in contrast to previous forms of slavery, where slaves were primarily prisoners of war who were freed after a period of time. Initially, European colonists attempted to enslave Native Americans; however, Africans, because of their lower susceptibility to diseases and easy identification based on skin color, proved to be a more profitable economic commodity (Franklin, 1994). Also, colonial plantation owners served their own interests by elevating their White indentured servants to a higher position than Africans. By providing psychological race-based privileges for marginalized White groups, they largely precluded dissatisfied Black and White workers from revolting together against the landowners (Steinhorn & Diggs-Brown, 1999). This racial division, thwarting a natural coalition of economically marginalized peoples, continues in U.S. politics to this day.

As early as 1622, many of the American colonies passed antimiscegenation laws to preserve these racial boundaries; however, these did not apply or were not enforced with respect to male slave owners and their female slaves. It was not at all unusual for these slave owners, usually aristocratic and propertied White men, to coerce sexual relationships with Black women slaves. The offspring of these coerced relationships further augmented the skin color hierarchy in America, as described by Russell et al. (1992) in *The Color Complex*. Children were classified as “mulatto” (one-half Black), “quadroon” (one-fourth Black), and “octoroon” (one-eighth Black; Izrael, 2001). During the era of slavery, slaves with a White father led a more privileged existence than their counterparts (Frazier, 1957). Lighter-skinned slaves were typically given more prestigious jobs, such as artisan or seamstress, and darker-skinned slaves did more physically demanding, menial work, often as field hands (Blackwell, 1985; Frazier, 1957).

This within-group color hierarchy created friction between many darker- and lighter-skinned slaves and gave rise to colorism in Black communities that has existed since. Skin color privilege continued throughout American society after the abolition of slavery. Educational, economic, and occupational opportunities were more accessible to light-skinned Blacks during the era of *de jure* segregation, often perpetuated by segregated Black institutions. Lighter-skinned African Americans often avoided marriage with darker-skinned individuals and maintained or desired to maintain closer ties with White communities (Hunter, 2004). They also formed social clubs, such as the Bon Ton Society of Washington, DC, and the Blue Vein Society of Nashville, which restricted access based on skin color. These societies adopted formal

and informal barriers to entrance, such as the “brown paper bag” test (skin tone had to be as light or lighter than the color of a paper bag), the “comb test” (a comb had to pass through hair easily), and painted doors (used to judge skin color). The formal traditions have since passed, but the names and legacy (i.e., practiced values) remain (e.g., “Blue vein”). Many major urban cities across the United States have areas that were historically inhabited primarily by light-skinned Black Americans; these were often the most affluent elements of segregated Black communities. For example, one area in Harlem, known as Strivers’ Row, housed a number of light-skinned doctors, lawyers, and other professionals. Historically Black colleges and universities also discriminated against applicants based on the color of their skin, using informal barriers such as the aforementioned paper bag test. Even relatively dark-skinned students admitted to institutions have been socially marginalized. All of these biases are driven by the implicit, unacknowledged (and often unintentional today) theme that Whiteness, and anything White-like, is superior, and Blackness, and anything dark, is evil or inferior.

Developmental Significance of Colorism: Skin Color Biases and Attitudes as Risk Contributors

Color consciousness and attitudes begin at an early age. Much of the early literature regarding skin color preference involved preschool populations (e.g., Clark & Clark, 1939). Clark and Clark (1940) found that Black children as young as 3 years old had knowledge of skin color differences and could appropriately self identify. It was posited that the children were not identifying on the basis of race because that concept was too advanced for their development. Instead, young children identified on “the basis of skin color which is to them a concrete reality” (p. 168). In a later experiment, children were given a Black and a White doll and were asked questions, such as which one they would “like to play with” or which one is the “nice doll” (Clark & Clark, 1947). The majority of the participants in that study demonstrated White preferences. The Clarks concluded that the response pattern indicated Black self-hatred, a finding that was cited in the Supreme Court’s 1954 landmark decision in *Brown v. Board of Education*. Other studies have found similar results, indicating that Black children display preferences for the color white and White people (Gopaul-McNicol, 1988; J. D. Porter, 1971; Williams & Roberson, 1967). However, the Clarks’ (1939, 1940, 1947) and contemporary studies have been criticized as having inaccurate interpretations or methodological flaws (Baldwin,

1979; Brand, Ruiz, & Padilla, 1974; Cross, 1991; Spencer, 1984; Spencer & Markstrom-Adams, 1990). Moreover, their interpretation of children's preference behavior reflected the ethos of Black pathology and deficit-oriented perspectives alluded to earlier.

In contrast to the Black self-hatred theory, other research has shown that despite having a White preference (for dolls, pictures, or other objects), Black children display positive self-esteem and self-concept (Banks, 1976; McAdoo, 1985; Spencer, 1984). In this literature, researchers maintain that Black children's personal self-esteem is independent or separate from racial preference behavior. Most of these studies actually assess self-concept and racial attitudes in the same population, rather than making assumptions, to delineate the relationship of the two constructs. For instance, Spencer sampled 130 Black preschool children between the ages of 4 and 6. She found that 80% of the sample obtained positive self-concept scores, while demonstrating pro-White biased cultural values. She concluded that Black preschool children separated personal identity (i.e., self-concept) from knowledge of racial attitudes. Similarly, Banks found that despite having pro-White attitudes, Black teenagers from predominantly White communities and schools still tended to have positive self-concepts.

As suggested by Spencer's (1982a, 1982b, 1983, 1984; Spencer & Dornbusch, 1990; Spencer & Markstrom-Adams, 1990) program of research, as opposed to those making negative inferences from the Clarks' studies and fomenting "self-hatred" conclusions (e.g., Kardiner & Ovesey, 1951; Pettigrew, 1964), in fact, young Black children may not internalize pro-White/anti-Black messages. The developmentally appropriate explanation credits the "protection" emanating from normal levels of cognitive egocentrism (Piaget, 1932). Spencer (1982a, 1984, 1985) notes that young children are appropriately self-centered and, in general, do not project their preferences inward; in fact, developmentally appropriate cognitive egocentrism serves as a protective factor that prevents the internalization of biased racial attitudes and, thus, generally precludes the acquisition of low self-esteem.

Cross (1991) notes that even in the Clarks' data, it is not clear that Black children systematically preferred White dolls, and in any case, their preference behavior shifted with age; this is not unexpected, given Spencer's (1985) integration of social cognition-dependent developmental processes into the analysis. That is, as children mature and increase their capacity to make inferences about cognitive, social, and affective phenomena, in effect and of necessity they shed what represented "protective ego-

centrism" and become more aware of how society views Blackness. Spencer (1999) describes developmental trends in color/race response patterns from four studies in different geographic regions of the United States. Data indicate that Black preschool children demonstrate Eurocentric attitudes, preferences, and color connotations through early middle childhood (approximately age 9). These attitudes and preferences reflect children's early learning that all things White are more valued in society. However, children do not necessarily internalize potential negative affect due to cognition-linked egocentrism. The onset of concrete operational thought marks a shift in attitudes and preference toward a more Afrocentric orientation. Of particular importance, the end of egocentric thinking can be a source of risk: Once Black children have the veil of protective egocentrism lifted, they begin not only to be aware of and understand societal attitudes and stereotypes of color, but to view themselves in light of them. Data suggest that given the protective character of cultural socialization, many Black children react to potential dissonance by shifting their preference behavior (i.e., becoming more Afrocentric; Spencer, 1983) rather than adopting low self-esteem; nonetheless, this shift itself diverts attention and psychic energy from other developmental tasks, such as academic engagement (see Spencer, 1999).

Nevertheless, the risks associated with race awareness and exposure to biased racial attitudes may be offset by protective factors. Black parents can, and often do, socialize their children to understand the importance and implications of their skin color. Spencer et al. (1997, p. 818) suggest that "minority parent child rearing efforts require, of necessity, providing explicit explanation of the meaning and significance of their youth's [color and] race." Racial socialization can be a protective factor by decreasing the psychological impact of hostilities based on color and race (H. C. Stevenson, 1994). Proactive socialization strategies encourage racial and cultural pride, and protective strategies focus on awareness of racism and related biases such as colorism. Some suggest that this is not just a protective factor but also a necessity for "raising physically and emotionally healthy children who are Black in a society where Black has negative connotations" (Peters, 1985, p. 161).

Color bias also has different implications by gender. For Black females, concerns about skin tone exacerbate the normative challenges of body image and appearance (Fegley, Spencer, Goss, Harpalani, & Charles, in press); these occur because of the greater importance placed on physical attractiveness for females generally. Moreover, the specific developmental period also plays a significant role, given that more general concerns about appearance increase for

all youth during adolescence. Thus, risks associated with colorism vary with gender, context, and development. Further, as suggested by Regan Good (2003), in an interview with Randall Kennedy concerning Kennedy's book *Interracial Intimacies*, structural impediments are linked to the persistency of the problem and concerted efforts across significant time will be needed for change.

Colorism and Stress Engagement: Tangible Experiences of Color Bias

For youth of color, experiences related to skin color bias are encounters of stress that must be negotiated in conjunction with normative developmental challenges. These are dissonance- and anxiety-producing experiences generally missing for Caucasian youth. That is, relative to individual context "fit," in general, the experience of consonant conditions is more often the norm. To illustrate, media images, stereotypical labels, and books all communicate skin color bias. Advertising of tanning solutions suggests enhancements and not as a negatively portrayed deficit. Russell et al. (1992) point out that light to medium skin tones (and terms used to describe light skin) are typically linked to intelligence and refinement, whereas dark skin tones suggest toughness, meanness, and physical strength. Historically, slogans and rhymes convey negative attitudes about Black skin tones (K. T. Brown, Ward, Lightbourn, & Jackson, 1998); one such catchphrase is "If you're White you're all right, if you're yellow you're mellow, if you're brown stick around, if you're Black get back."

In a 1972 study by Edwards, darker-skinned participants showed a slightly greater consciousness of racial discrimination than those of lighter complexions. Darker individuals also sensed greater hostility on the part of Whites than those of lighter skin tones. These findings are not surprising considering pro-White messages conveyed in American and other societies. These views are deeply embedded within social structures and serve to perpetuate contemporary beliefs of White supremacy.

By the onset of adolescence, Black youth have well-defined stereotypes about skin color (Parrish, 1946). C. Anderson and Cromwell (1977) focused specifically on positive and negative stereotypical attributes that are associated with skin color. Overall skin color preferences tended toward lighter-brown colors, although darker-skinned teens valued darker skin more highly and lighter-skinned participants valued lighter skin color more highly. Light brown skin was chosen for items that gauged positive characteristics, such as "the nicest, the one best liked to marry" (p. 80). Likewise, for the items that gauged nega-

tive characteristics (e.g., who was the dumbest, the person one would not like to marry), subjects selected dark skin. As noted, such encounters experienced by youth of color suggest an extension and exacerbation of stress related to body image and physical appearance that, in general, all adolescents experience and cope with.

Color biases can also worsen stress in the realm of interpersonal relationships, where skin color may represent a source of acceptance or rejection. The significance begins at birth. As Russell et al. (1992, p. 94) note, "Many Black families can barely disguise their anxious concern about the color and features of a newborn." Given anticipated additional stress, families may pass on their anxieties about structural impediments associated with skin color as specific attitudes. Moreover, cultural socialization efforts that specifically communicate the history of skin color bias to children along the hierarchical system of slavery that produced it vary widely; accordingly, attitudes about skin tone vary (Boyd-Franklin, 1989). Given the dissonance-created character of skin color as a topic, relative to family responses, the relationship is neither simple nor obvious. In some families, light skin color is prized in accordance with societal biases; however, other Black families may develop different preferences, conscious or unconscious, in light of historical influences such as the Black Power movement. In these families, dark-skinned members are preferred and light-skinned members may be viewed and subtly chastised as shameful reminders of slavery and miscegenation.

Albeit sometimes hidden and independent of developmental period, skin tone continues to affect relationships. For example, in a study involving two groups of undergraduates and a group of graduate students at a historically Black university, Marks (1943) discerned that classmates who were lighter than average, but not at the extreme light end of the color spectrum, were perceived as most attractive and charming. Correspondingly, in another experiment, very dark brown and dark brown skin tones were least favored (C. Porter, 1991). Other skin color studies have shown that medium complexions are preferred over the extremes. According to C. Porter, regardless of age or gender, children prefer honey brown tones to darker skin tones. She suggests different gender- and age-related rationales for preferences based on cognitive development, broadening intergroup social experiences, and specific developmental concerns. Children between the ages of 9 and 11 offered reasons related to desire for sameness and desire to be liked by others (e.g., "her friends are that color" and "wants to be like everyone else"). Older children, 12- to 13-year-olds, explained their preference based on physical attractiveness (e.g., "probably thinks she's ugly with that

color”) and the possibility that people are discriminated against on the basis of skin tone (e.g., “could get more jobs and people would talk to her more”). These findings underscore the significance of normative developmental tasks, such as forming peer relationships, in mediating the impact of skin color biases.

Skin color is, or is perceived to be, a factor in selecting romantic and marital partners (Bond & Cash, 1992; Hughes & Hertel, 1990; Hunter, 1998). In a study with Black undergraduate females attending a southern university, the women were asked about their perceptions of skin color as an influence on mate selection (Bond & Cash, 1992). Regardless of their own skin color, most of the females believed that Black males preferred women with lighter complexions. Not only are light-skinned women preferred as mates, they are more likely to marry higher status husbands (Hunter, 1998). In their study, Hughes and Hertel reported that controlling for age, gender, education, occupational prestige, and parental socioeconomic status, light-skinned women were found to have a spouse with more education and higher occupational status. Obviously, the attainment of resilience (i.e., given the problem of structurally organized and long-term biases) requires specific coping strategies and supports.

Coping and Identity Challenges Related to Colorism

As noted previously, normative cognitive maturation makes awareness of dissonance concerning color bias both unavoidable and potentially acute. Reactive coping responses to experienced dissonance and potential problems lead to the enactment of strategies that may be either adaptive or maladaptive. Spencer (1995) posits that perceptions of self and thoughts about how others perceive you influence behavior. Therefore, internalizing skin color bias can influence psychological equilibrium and require particular coping strategies. Determining how people perceive and interpret the meaning of their skin color is important for understanding coping processes and specific supports required.

On the psychosocial level, studies suggest that skin color is related to perceptions of attractiveness, self-esteem, and satisfaction. Stress related to body image and physical appearance may be among the most palpable manifestations of skin color bias. A basic conclusion drawn in the early research was that lighter skin color was valued more than darker skin color and the valuing of certain skin tones negatively affected self-esteem, especially in children. However, given developmental differences in young

children’s cognition, the inferences are not consistent with empirical demonstrations. Specifically, consistent with the doll studies, one should not assume negative outcomes in this domain; stress and coping responses to stress vary significantly within groups given variations in parental socialization strategies and early childhood experiences. Although focused on a very different developmental period, more recently, Coard, Breland, and Raskin (2001) examined the role of skin color as it pertained to self-esteem among 113 Black college students of various skin tones. The authors hypothesized that perceptions of and preferences for darker skin color would be positively related to higher levels of self-esteem, whereas perceptions of and preferences for lighter skin would be positively related to lower levels of self-esteem. In contrast to their hypothesis, they found that the more satisfied darker-skinned males were with their own skin color, the lower was their self-esteem. They suggest two possible explanations for their finding. First, for these dark-skinned males, satisfaction could exist on an intellectual level, but emotional inner conflict may still exist. Second, and more interesting, they suggest that dark-skinned individuals felt satisfied with their skin color, but believe others (Blacks and Whites) perceive their dark skin negatively. Coard et al. contend that given the importance darker-skinned participants attributed to others’ ideals, it is understandable that their self-esteem was compromised and reported as lower. However, as cognitively sophisticated young adults who do not deny or reject the fact of their own skin color, the findings might suggest that exposure to and awareness of social stereotypes, when considered together, may result in more dissonant sources of feedback for consideration in normative psychosocial processes.

Similarly, using a young adult sample, Altabe (1998) studied body image and skin color in a racially diverse sample of college students using the Physical Appearance Discrepancy Questionnaire (Altabe, 1996); this measure asks respondents about their own physical appearance, ideal body image, and perception of physical traits believed most valued by their cultural group. Skin color was noted as a salient trait by all racial/ethnic groups in the sample: Black, White, Asian, and Latino. Asians reported valuing light skin the most, followed by African Americans. Conversely, all groups except Black females and Asian males responded that having a darker shade of skin color is on their list of the top five ideal traits. However, in the analysis of cultural values of attractiveness, 23.5% of Asians and 21.2% of Black Americans listed light or lighter skin as a culturally valued trait compared to 10.5% of Latinos

and 8% of White Americans, who listed light or lighter skin tone as a trait valued by their culture (10.5% and 8%, respectively). In a study of adolescents, Fegley, Spencer, Goss, Harpalani, and Charles (in press) found that consonance and dissonance (i.e., respectively, satisfaction and dissatisfaction with skin tone) was more significantly related to a variety of measures of psychosocial well-being, including body image, than was skin tone itself. In their multiethnic sample, darker-skinned individuals were more likely to be dissonant than lighter-skinned individuals, although individuals rating their skin tone in the middle showed the greatest amount of satisfaction. Fegley et al. also found Asian/Asian American youth to be the most dissonant with respect to skin tone, and lighter-skinned individuals (of all racial/ethnic groups combined) had lower overall body image and less general positive attitudes. Although not speculated about by the authors, perhaps the latter finding is in fact in keeping with media images of lighter-skinned persons and advertisements that focus on body image perfection, thus again subliminally suggesting a downside of privilege (i.e., sets of subliminally communicated problems associated with possessing stereotypically valued physical attributes).

These findings indicate that the relationships among colorism, coping, and psychological well-being are not independent of cognitive functioning and developmental status and, considered overall, are more complex than one might predict based strictly on societal biases. For immigrant populations, national origin may play a role; for example, Montalvo and Codina (2001) found that relatively dark-skinned Mexican Americans (born in the United States) had lower self-esteem scores than dark-skinned Mexicans born in Mexico. Future work can help link color biases and attitudes along with racial socialization more directly to racial and ethnic identity. Skin color, color biases, and related racial/cultural socialization have evident implications for the different phases of Cross's (1991) nigrance model, along with other racial/ethnic identity theories (Helms, 1990; Phinney, 1992); however, as suggested, the relationships are significantly more intricate than might be predicted based solely on societal biases.

This research underscores the necessity for a comprehensive, culturally and contextually sensitive framework of human development. As part of the normative developmental processes associated with adolescence, youth negotiate challenges associated with physical appearance and societal standards of attractiveness; without a doubt, color biases exacerbate these challenges for darker-skinned youth of all ethnicities. However, many of these youth are able to

cope successfully and to maintain positive feelings about self, as one might expect from a normative (as opposed to pathological) developmental perspective. Nonetheless, societal biases affect how youth are treated and, as illustrated in the next section, as consistently experienced social impediments, may affect their life chances.

Colorism and Life Outcomes

Empirical studies have illustrated that color bias can have an impact in multiple domains of life outcomes. For example, in the realm of education, studies have historically shown that in general, lighter-skinned Black Americans complete more years of formal schooling than their darker-skinned counterparts. Reuter (1917), for example, noted that 11 out of the first 12 Black men who received doctoral degrees from American universities were of interracial parentage. As noted earlier, predominantly Black universities historically discriminated against applicants based on their skin tone. Schools for light-skinned individuals stressed a liberal arts education, and schools populated by dark-skinned students were mainly oriented toward vocational training (Maddox, 1998). Lighter-skinned African Americans were more likely to engage in scholarly pursuits, and dark-skinned individuals prepared for vocational trades. Thus, lighter-skinned individuals (and often those of interracial background) had greater access to education—already a restricted commodity for all Americans and especially African Americans (Maddox, 1998).

Skin tone disparities in education, although generally unacknowledged, still exist. Studies indicate that lighter skin is positively correlated with education (Hughes & Hertel, 1990). Light-skinned Black Americans complete more years of schooling, on average, than their darker-skinned counterparts even when controlling for gender, age, and parental socioeconomic status. Keith and Herring (1991) report that educational attainment increases as skin color becomes lighter. In their study, they used interviewer assessment of participants' skin color. Each skin color increment, as assessed by the interviewer, corresponded to one-half year of additional education. On average, "very light" respondents attained approximately 2 additional years of education over "very dark" respondents.

Income and occupational attainment is another area where color disparities are still apparent. Hughes and Hertel (1990) note that the effect of skin color on the salaries of lighter versus darker African Americans is as great as the effect of race on the earnings of White Americans and all Black Americans. The family income for those with

lighter skin was reportedly 50% more than for those families of darker-skinned Blacks (Keith & Herring, 1991). Additionally, Keith and Herring found that the personal income of light-complexioned African Americans was 65% greater than their darker-skinned counterparts, and light-skinned people were more likely to be employed in professional and technical positions, whereas individuals with dark complexions were more likely to be employed as laborers. These findings suggest that, when considered jointly, colorism and racism are life course-relevant obstacles to the long-term resilience of many racially and ethnically diverse youth. Skin color among offspring even within families remains a genotypic determining outcome; colorism themes in general are sensitive, complex, and, infrequently overtly discussed issues. Accordingly, parents are less likely to consciously and proactively focus on the training of nuanced cultural socialization tactics that would serve as protective factors as youth transition across time and place. However, many parents manage the challenge and, thus, enhance the resilient outcomes of their offspring. In general, when considering vulnerability and resilience, the topic of colorism as linked to cultural socialization across ethnic groups continues to need programmatic, sophisticated, and nuanced research efforts approached from a developmental perspective. Enhanced variability between and within groups due to special situations such as immigration status (and its timing) further complicates the issue and thus contributes to the issues of risk and vulnerability if not offset by equal levels of protective factors experienced as supports.

VULNERABILITY AMONG RACIALLY AND ETHNICALLY DIVERSE YOUTH: CULTURAL DISSONANCE

Based on basic tenets of classic dissonance theory, cultural dissonance refers to the cognitive and emotional stresses resulting from conflicting cultural values or norms confronted by individuals in culturally salient situations; they are hypothesized to be linked with social cognitive processes (see Spencer, 1982a, 1982b, 1984, 1985; Spencer & Markstrom-Adams, 1990). Cultural dissonance can take a variety of forms and be expressed through multiple domains of human development. Cultural practices that vary among groups are potential sources of cultural dissonance. Further, increases in rates of immigration within race may potentially exacerbate complex within-group cultural variation and dissonance as well. Unfortunately, underanalyzed perspectives are prevalent. The

points of view ignore developmental processes, including youths' own perceptions, historical factors, and contextual conditions. The shortsightedness interprets "achievement gaps" as emanating from youths' internal characteristics as opposed to linking them with long-standing issues of *absent privileges* for some and a history of unacknowledged and intergenerationally transmitted broad privileges for others (see critical reviews and critiques by Spencer, 1999, 2001; Spencer, Cross, et al., 2003; and Swanson, Cunningham, & Spencer, 2003).

As illustrated by inferences made by Ogbu (1985) and colleagues, the implications of shortsighted misinterpretations of performance differences both within and between groups further complicate the design and implementation of social supports. Ordinarily overlooked has been the salience of stereotype threat for group performance patterns (see Steele, 1997, 2004; Steele & Aaronson, 1995). Stereotype threat experienced by second-generation youth versus the perceptions and consequent coping of more recent immigrants provides the case in point. We suggest that when considered within ethnic groups, immigrants may perceive and experience differences in apparent sources of risk and psychological and social resource availability, which, considered together, potentially exacerbate overall vulnerability level (see Spencer, Kim, & Marshall, 1987). Accordingly, we consider selected themes to illustrate vulnerability associated with cultural dissonance.

Because the experiences of immigrants vary substantially by generational status, scholars distinguish between *first-generation* immigrants (or Americans), who were born overseas, and *second-generation* Americans, who are born in the United States as children of immigrants. The term *1.5 generation* is sometimes used to describe youth who were born abroad but who arrived in the United States at an early age (usually before adolescence); these youth are technically first-generation Americans but share many of the experiences and challenges of the second generation.

The changing patterns of immigration along with the consistent fact of social cognitive development have rendered cultural dissonance among youth an even more important issue than considered in the past. Immigration accounts for a substantial percentage of U.S. population growth (Camarota, 2001); in particular, immigrant and second-generation children represent the fastest growing segment of the country's total population under the age of 18 years (Portes & Rumbaut, 2001). Previous waves of immigrants to the United States came mainly from European countries; although they faced many challenges, assimilation was more accessible to them because of greater phenotypic similarity to the hosts, greater cultural consonance

between European and White American norms, and legal definitions of Whiteness, which dictated eligibility for citizenship (Haney-Lopez, 1996). The passage of the 1965 Immigration Act has led to over 40 years of sustained legal immigration, particularly from Mexico, Central and South America, the Caribbean, and East and South Asia; accordingly, there has been a significant increase in the size of the nation's population of people of color (Portes & MacLeod, 1999).

Of course, the exact nature and experience of cultural dissonance is dependent on the two sets of cultural norms or values that are in conflict; in the United States, this usually involves middle- or upper-middle-class White American values conflicting with some other set, as the former is usually considered the unacknowledged norm for all. This is also an area where it is necessary to distinguish finely between race and ethnicity, as there is tremendous ethnic variation within socially and politically constructed racial groups. Moreover, factors such as immigration history and socioeconomic status also impact the experience of cultural dissonance. In addition to the generational classification noted earlier, John Ogbu (1978, 1985, 1990) presents a controversial historical framework to understand the social and political positions of various racial/ethnic groups in the United States. He classifies American minorities into three groups. *Autonomous minorities* are small numerical groups that self-identify as a minority group in salient ways (e.g., Jews, Mormons). These groups are generally established populations in the United States, but they may continue to face forms of discrimination. *Immigrant minorities* are those who voluntarily come to the United States and have expectations of upward social mobility (e.g., many but not all Asian immigrant groups). As conceptualized by Ogbu (1985), *subordinate or caste-like minorities* were involuntarily incorporated by White Americans through slavery or subjugation (e.g., Blacks, Native Americans).

Ogbu's framework specifies the varying historical relationships that different groups have with the United States. These structured relationships influence opportunity and desire for assimilation, along with other factors in the negotiation of cultural dissonance. However, a major critique of Ogbu's conceptual strategy is its penchant to make simplistic, deterministic assumptions about group psychology and cultural behavior from such sociohistorical taxonomies (Ogbu, 1985; Fordham & Ogbu, 1986; for critiques, see Harpalani, 2002; Spencer, Cross, et al., 2003; Spencer et al., 2001). Within-group diversity is a key issue when examining the historical, cultural, and political circumstances of racial/ethnic groups and resultant experiences and coping strategies required for health and psychosocial adjustment.

For example, Latinos would be split across Ogbu's categories of minority groups (see Gonzales, 2000). Many are recent voluntary immigrants and thus would best be described as immigrant minorities (e.g., recent immigrants from Central and South America), and some have the additional challenges associated with refugee status (e.g., Cuban Americans). Others fit better in the category of subordinate minorities (e.g., Puerto Ricans, some Mexican Americans). It is important to understand the historical relationship of particular Latino groups to this country and also to note within-group variation even if historical circumstances are the same; stress engagement associated with cultural dissonance can fluctuate (due to protective factors and their actualization as social supports), and coping strategies can also vary.

Similarly, Asian American groups have diverse immigration histories. Although most (but not all) Asian Americans can be described as immigrant minorities, there are significant differences in their particular immigration histories—even within particular groups (Prashad, 2000; Takaki, 1998). The historical era of immigration is particularly significant. Waves of immigrants from Japan, China, South Asia, and other regions began coming to the United States in the late 1800s. Immigration from these areas was outlawed by the early 1920s, but descendants of these early immigrants remained, and many have retained their particular ethnic identity rather than assimilating completely (Takaki, 1998). When Asian immigration occurred in significant numbers after 1965, the immediate waves of immigrants were largely educated professionals who secured immigration through occupational preferences; this wave laid a large part of the foundation for the "model minority" myth of Asian American academic achievement. However, more recent Asian immigrants have arrived largely on family preferences rather than occupational status; they are often less educated and work in lower status jobs. Of great significance is that stereotypes such as the model minority myth can obscure the challenges faced by this group given significant sources of within-group variability. Attempts to homogenize the group's experiences draw attention away from the larger issues of cultural dissonance faced by many Asian American youth regardless of their educational and socioeconomic backgrounds. Accordingly, attempts to understand and support psychosocial processes are undermined.

Cultural Dissonance as a Risk Contributor: Individualistic versus Collectivist Societies

Societies are characterized by sets of cultural norms that vary and are always evolving. The differences between norms in and across societies can also be described in

different ways. One such designation that may be useful to consider is the rubric of individualistic versus collectivist societies (Donde, 2001). *Individualistic* societies, which include the United States, tend to follow an ideology that revolves around personal autonomy, independence, and self-reliance. These societies purport to value individuals who are able to separate themselves from others and from situational contexts. The independent self is constructed to be a fixed entity that supposedly does not change with social situations: "The independent self-system thus seeks to display or assert attributes or features of the self. Others in a social situation are important, but their importance is represented primarily as standards of social comparison or for feedback that can validate the inner attributes of the self" (Markus & Kitayama, 1991, p. 22). Of course, individuals may not always display such individualistic attitudes and behavior, but in an individualistic society, the collective social norms and values center on expectations of such independence.

Collectivist societies, on the other hand, strive to emphasize obedience and conformity. The primary stated goal in these societies, which include many Asian countries, is to shape individuals into *interdependent beings* who are defined by their relationships. The interdependent self is perceived as "fluid" (i.e., able to change when the social environment around one changes). As described by Markus and Kitayama, interdependent individuals are dynamic and defined by roles according to situation and context: "Such an interdependent self is not properly characterized as a bounded whole, because it changes structure with the nature of the particular social context" (in Markus & Kitayama, 1991, p. 23). Again, individuals in a collectivist society may not always model such attitudes and behavior, but this is the stated norm in a collectivist society.

Given the large differences inherent between these two types of societies, it is highly probable that immigrants from collectivist societies who move to the United States may experience cultural dissonance and show difficulties in adjusting to their new surroundings. When individuals choose to immigrate, they may come with practical knowledge of the country to which they are moving, but many will not be learned in the cultural and societal values, beliefs, and attitudes of the foreign country they are adopting as their new home. Even to the extent that they are aware of these, actual experiences of cultural dissonance present new social and psychological challenges for immigrants.

Moreover, these challenges are in some ways compounded for the children of immigrants, the second generation. Immigrants may already have a strong sense of ethnic

identity and self from experiences in their native land; although cultural dissonance poses a challenge, they can draw on their own cultural capital as a resource to promote adaptive coping. The second generation, however, must undergo the challenges of identity formation *at the same time* as they are experiencing cultural dissonance; in fact, the normative challenges of identity formation are exacerbated by cultural dissonance for second-generation youth.

Stress Engagement Related to Cultural Dissonance

On a regular basis, tangible experiences of cultural dissonance create a "clash of cultures" for many immigrant and second-generation children. Mehta (1998, p. 133) addresses these processes specifically for Asian and South Asian American youth: "The second generation has been exposed to distinctly different language, goals, food, rituals, dress, music, landscapes, and values than their parents. There is a strong urge to retain ethnic identity while rapidly acquiring awareness of American values, partially due to financial gains." Because of this disparity between their ethnic identity and their national identity, these children face a salient tension: the collectivist ideologies from valued families constantly coming into conflict with individualistic ideologies from the surrounding environment. While navigating across varied social settings and associated social traditions, immigrant and second-generation children and adolescents must grapple with normative developmental tasks while also confronting the difficult chore of successfully juggling opposing philosophies. There is inadequate developmental research on the specific content of the cultural socialization techniques proven effective for abating the additive and consequent tensions experienced by youth.

Two of the most salient areas where such conflicts come into play are in the choice of career and romantic relationships, as these are two areas that can have long-term effects on the nature of relationships between parents and children. Given the different expectations of male and female children in many societies, gender can pose an additional risk here, exacerbating the tensions created by cultural dissonance. For example, some Asian and South Asian parents may be more protective of female children with regard to dating. Asian American children confront a social environment in the United States, including school, university, peer groups, and the media, that teaches them to exert autonomy and independence and to follow their own aspirations and desires. Youth recognize the availability of many options and are encouraged by American society to choose

for themselves among these. However, many Asian American children are also expected to obey their parents and fulfill their obligations to their families. Emphasis on autonomy and self-sufficiency is frequently misinterpreted by immigrant parents as selfishness or lack of caring (Mehta, 1998). As Eng (1999) notes, immigrant parents often feel that they have made many sacrifices for their children; they may employ guilt to compel children to follow their wishes. Many Asian American youth face these struggles; however, particularly for youth of color who are most vulnerable to the experience of cultural dissonance, it is critically important not to make deterministic assumptions about the experiences of immigrant and second-generation youth or their parents. With proper understanding, both parents and peers or significant adults outside the family can serve as sources of support that help youth negotiate the varied sources of cultural dissonance.

It is imperative to note that immigrant parents themselves also continue to undergo a process of identity development; the duality of the role indicates that while being culturally socialized themselves by their children, and while adjusting their views, at the same time parents must engage in the normative parental task of socializing their children. In some families, it is possible for parents to accept and feel comfortable with their children's choices to adapt and conform to their American surroundings. However, new situations and challenges arise throughout youth development that are fairly typical: dilemmas over schoolwork and friends, dating, college and career decisions, and marriage and childbearing. Parents may be more open-minded about some of these areas than others, and children may adopt different cultural values in these various domains.

Coping and Identity Issues Related to Cultural Dissonance

For various reasons, cultural dissonance is unavoidable for many youth. Cultural conflicts between immigrant parents and their children often reflect different belief systems; there are no necessarily right or wrong solutions to these conflicts. Also, as H. C. Stevenson (1997) notes, cultural dissonance is not limited to immigrants and their children. Due to differences in context and the cultural meaning of particular behaviors and sociocultural traditions (e.g., music, dress, dance, and adolescent social relations), as previously noted, many urban African American, Hispanic, and Native American youth may be compelled to employ different coping strategies across school and neighborhood settings. Of salience is that, as typically deployed by ado-

lescent-stage individuals, particular adaptive coping strategies may seek to manage such dissonance rather than resolving it completely.

Phelan et al. (1991) present one framework to help explain issues of cultural dissonance; they define four patterns of interaction with regard to school, family, and peer transitions. In the *congruent worlds/smooth transitions* pattern, social norms, expectations, beliefs about the world, and other factors that shape daily interaction are relatively consistent across school, peer, and family settings. Normative developmental challenges are present, but these are not exacerbated by cultural dissonance, as the larger social and cultural factors are congruent. This congruency pattern may be more common among many White, middle-class youth. Another type of interaction is *different worlds/boundary crossings managed*. In this category, norm and value differences exist across settings, but these are not very great, or they are managed adaptively. One may refer to this particular type as porous as there is more commonality across the settings. In the *different worlds/boundary crossings hazardous* state, youth view their school, family, and peer settings as distinct with regard to cultural norms, suggesting clearly nonporous conditions with significant consequences for transgressions. Language barriers may be salient, and parental values may be significantly different from those encountered in school. These two "different world" profiles are more common among immigrant youth, and the difference between the two may be a matter of available social supports. One should add that the level of cultural awareness, content and sensitivity of professional training, and character of role portrayal clearly play significant roles relative to the adults' contributions as potential sources of support. The too frequent and valid reality is that all labeled supports, when considered from youths' phenomenology, may be actually experienced as neither user-friendly nor reliable sources of support.

In the last of their categories, *borders impenetrable/boundary crossings insurmountable*, Phelan et al. (1991) note that values, beliefs, and expectations across settings are characterized by so much cultural dissonance that interactions across settings are extremely difficult or not possible. The authors note that youth may resist crossing boundaries between settings altogether, leading to negative outcomes such as school failure or rejection by peers. As policies and incentive-linked practices, these situations may require even more social support to allow youth to cope adaptively and for adults to perform more responsibly. In fact, this suggests an exemplar condition that requires both *proximal adult and broad systems recognition*

of the condition's problematic character for youth competence. Additionally, the situation suggests the needed introduction, monitoring, and evaluation of culturally sensitive and effective intervention strategies.

Considered proactively, the last two categories (i.e., different worlds/boundary crossings hazardous and borders impenetrable/boundary crossings insurmountable), more often than not, require a full and open discussion of race, social class (i.e., as resource availability), gender, and ethnicity-associated issues. Each introduces significant degrees of uncomfortableness for adults and policymakers. Consequently, the foundational concerns articulated by Phelan et al. (1991) are very seldom directly or indirectly addressed, although "gap" portrayals are prominently discussed in the news media. The systemic outcomes of effects and inferred invisibility of the issues merely contribute to stereotypes and an exacerbation of the troubling border-crossing concerns described. The situation obfuscates youths' opportunities because the undergirding contributors of cultural dissonance are neither adequately understood nor ultimately addressed.

Although cultural dissonance poses a significant source of stress for many youth of color, as suggested, proper (i.e., strategically implemented) resources enhance its successful negotiation. It is important for these youth to develop a strong sense of identity so they can maintain a coherent sense of self across dissonant settings. In addition, we should remember that youth in the first category, congruent worlds/smooth transitions, are also vulnerable; in fact, the aforementioned downside of privilege may be relevant here. In lieu of challenges requiring the negotiation of some cultural dissonance, these youth may not develop the coping skills needed to cross cultural boundaries, and they may not learn to be comfortable when placed in the minority status or other conflict-generating situations (e.g., gender-based changes in the roles available to women). With the growing diversity of the American population, these skills are becoming increasingly important and, when present, potentially serve as protective factors.

Identity challenges relating to cultural dissonance have historically been viewed in light of the "melting pot" ideal, emphasizing assimilation. The straight-line assimilation model was developed in response to European immigrants' process of ethnic identity assimilation. In this model, individuals' identification with mainstream U.S. culture increases with succeeding generations as identification with their native culture decreases. However, theorists believed that the straight-line model of assimilation ignores the assimilation process of immigrants of color (Portes & Böröcz, 1989). A model of segmented assimilation has

been proposed to reflect immigrant minorities' process of assimilation; in this model, immigrant and second-generation youth have more options in terms of identity development (Zhou, 1997).

Portes and Rumbaut (2001) investigated the ethnic identity of immigrant and second-generation youth in their Children of Immigrants Longitudinal Study (CILS). The original sample for this study in 1992 included 5,262 eighth- and ninth-graders from Miami/Ft. Lauderdale, Florida, and San Diego, California. A follow-up survey in 1995 included 4,288 of the original participants. The largest immigrant groups represented in the sample were Cubans, Haitians, Nicaraguans, and West Indians in South Florida and Mexicans, Filipinos, Vietnamese, Laotians, and Cambodians in California. The sample was evenly divided with respect to gender, year in school (8th, 9th), and birth status (foreign-born/U.S.-born). Researchers conducted 54% of the interviews in Miami/Ft. Lauderdale and 46% in San Diego.

Portes and colleagues conceptualized immigrant youth ethnic identity in terms of four categories: national identity, hyphenated American, American, and panethnic. A *national identity* (e.g., Chinese) reflects identification with the native country; *hyphenated American* (e.g., Chinese American) reflects a bicultural identity that incorporates features of the homeland and the United States; *American* identity reflects lack of connection with the original homeland and an adoption of "American" values (referring to White American cultural norms); *panethnic* identity (e.g., Asian) refers to a denationalized identification centered on the political context of American racialization (Portes & Rumbaut, 2001; Rumbaut, 1994). These identity categories illustrate the segments of the population that immigrant identity youth can identify with as they assimilate into the United States.

In CILS, adolescents who were nationally identified were more likely to be first-generation or 1.5-generation immigrants (Kasinitz, Battle, & Miyares, 2001; Portes & Rumbaut, 2001; Rumbaut, 1994; Waters, 1994, 1996). Males and youth with two foreign-born parents born in the same country also were more likely to be nationally identified. Living in two-parent families in which both parents are foreign-born is presumed to enhance children's exposure to their native culture and provide a consistent cultural socialization message (Portes & Rumbaut, 2001). Youth living in upper-middle-class families were also more likely to identify nationally because they may have more reason to associate pride and honor with their ethnic identity (Rumbaut, 1994). In addition, parents' economic advantage serves as a protective factor, as they can provide their

children with resources to reinforce their ethnic identity, such as trips back to the family's country of origin and involvement in ethnic social organizations. Also, as demonstrated by Cuban immigrants in Miami, economically advantaged families can provide their children with private, bilingual education, which serves to reinforce youth's ethnic identity (Portes & Rumbaut, 2001). Nationally identified immigrant youth report feeling connected to their home country because they had strong family ties there, made frequent trips back, and had plans to return to live as adults (Waters, 1994, 1996).

Portes and Rumbaut (2001) also note the influence of political context on ethnic identity. Specifically, the Mexican-origin students in the California CILS sample showed an increase in choosing to identify as Mexican that coincided with the creation of Proposition 187. Proposition 187 sought to deny undocumented immigrants' access to social and nonemergency health care services and public school education (Portes & Rumbaut, 2001). Mexican-origin participants who identified as Mexican did so largely in reaction to the threat posed by Proposition 187. Their identity choice was also an outgrowth of their increased collective political activity to prevent the passing of Proposition 187.

Youth who chose the hyphenated American identity status were more likely to be female (this finding was specific to the first wave of data collection), born in the United States, and to have one parent born in the United States and the other parent born abroad (Rumbaut, 1994). Females' choice of a hyphenated American identity may be the outgrowth of their greater desire to incorporate all aspects of their experiences into their identity, whereas males, in a quest to simplify their lives, may be more likely to choose one identity over another (Rumbaut, 1994). Classic second-generation youth (children who are born in the United States to immigrant parents) may also choose to adopt a hyphenated American identity as a means to cope with pressure to identify with either their parents' or American culture. Similarly, maintaining a bicultural identity in the presence of one foreign-born and one U.S.-born parent may also constitute a strategy to cope with cultural dissonance (Rumbaut, 1994).

Additionally, those with an American identity reported being more embarrassed when their parents did not know or follow American cultural norms. They also reported a preference for English and chose to solely speak English with their close friends (Rumbaut, 1994). Further, American-identified youth were most commonly found in suburban schools and had a more positive view of the United States in regard to factors such as racism (Portes & Rumbaut, 2001).

Finally, those youth choosing a panethnic identity were more likely to be living in inner-city neighborhoods and to be attending inner-city schools with native U.S.-born minorities (Portes & Rumbaut, 2001; Rumbaut, 1994; Waters, 1994, 1996). It is possible that minorities with an immigrant background chose to identify with native-born minorities to fit in and also because they did not perceive the two groups as being dissimilar (Rumbaut, 1994; Waters, 1994, 1996).

In fact, with regard to race relations, panethnically identified youth, particularly Black and Latino adolescents, expressed greater awareness of society's negative perceptions of visible minorities, along with the categories of racialization in the United States (e.g., Asian American; Portes & Rumbaut, 2001; Rumbaut, 1994; Waters, 1994, 1996).

Consistent with a segmented assimilation model, data from CILS demonstrates that the process of ethnic identity for immigrant youth is not simple and suggests a dense web of context-linked psychosocial processes. From our view, a phenomenological perspective is necessary to understand more fully this process. Youth who are phenotypically similar may choose to identify differently. Developmental trajectories are also important to note; in CILS, 56% of participants reported different identities during both the first and second waves of data collection. National identity had the most overall stability, and participants who reported discrimination were also more likely to have a stable ethnic identity. Having both parents born in the same country and speaking the parental language also increased the likelihood of identity stability across time, and females were more likely to show stability in identity than males (Portes & Rumbaut, 2001).

Of course, much future research is necessary for a more thorough and nuanced understanding of the identity processes of immigrant and second-generation youth. Moreover, a development-sensitive theoretical strategy should inform the process. An integrated sociological delineation of identity with psychological models such as those of Cross (1991), Phinney (1992), and Helms (1990) would benefit segmented assimilation models. In addition, reflecting the various components of PVEST, more developmentally sensitive theorizing will support future research efforts.

Cultural Dissonance and Life Stage Outcomes

Cultural dissonance has implications for developmental outcomes in a variety of domains, including education, health, and psychological well-being. However, its impact is further mediated by structural impediments represented by neigh-

borhood character, family resources, and social policies (e.g., socioeconomic opportunities and immigration status) and by protective factors (e.g., cultural capital, social and economic supports). With respect to depression and self-esteem, Harker (2001) and Rumbaut (1994) reported that first- and 1.5-generation immigrants had more positive outcomes than second-generation youth. One possible explanation for this is that first-generation immigrants reported greater levels of parental supervision and social support. Another possibility is that the two groups have different referent others (Rumbaut, 1994); first- and 1.5-generation youth may compare their circumstances with those of people in their native country, as they were born there and have spent some time living abroad. They may feel that their situation is a significant improvement and, accordingly, not view or experience cultural dissonance in as significant a light. Conversely, second-generation youth are less likely to utilize their parents' home country as a point of reference, and cultural dissonance may be a primary concern. Another explanation may be the role of cultural socialization and pride. In fact, Zhou (1997) examined within-group ethnic identity differences in self-esteem for Vietnamese immigrants and found that Vietnamese adolescents who either identified as Vietnamese or Vietnamese American had higher self-esteem than American and pan ethnically identified students. Zhou attributed this finding to tighter cultural connections and social support among the former groups.

Kao (1995) explores educational achievement among Asian American youth; her findings indicate that achievement for most Asian immigrant groups is largely impacted by socioeconomic status and family characteristics. Kao's findings refute the model minority myth of Asian American academic achievement. A narrow focus on the educational success of Asian American youth in fact detracts attention from the social and cultural dissonance they may experience among peers. This is an area that requires much more research. Moreover, research questions that focus on and explore the experiences of low-income Asian youth, as well as other ethnic groups, who do well academically and enjoy positive peer relations also deserve scholarly attention as resilient young people.

COMPETENCE-PURSUING AND RESILIENCE-DEMONSTRATING OUTCOMES AMONG RACIALLY AND ETHNICALLY DIVERSE YOUTH

Robert White's (1959, 1960) classic theorizing concerning competence and effectance motivation suggests their pres-

ence as part of basic human functioning. Consistent with historical reviews (see Cross, 1979, 1991, 2003; Spencer, Cross, et al, 2003), research studies demonstrate that independent of objective social or economic resources available, parents and youth generally value academic success and have high aspirations for future attainments (e.g., Spencer, 1983 1990; Spencer et al., 1993). Additionally, the several reviews presented suggest that for various reasons (e.g., immigration status), racially and ethnically diverse youth may be differentially burdened with adverse experiences given particularly structured social conditions included as impediments for some and unacknowledged privileges for others. Regarding the former (i.e., experienced impediments and systematic challenges), the consequences for some may be associated with feelings of cultural dissonance and perceptions of insurmountable challenge. On the other hand, although generally ignored by media, many others demonstrate marked achievement independent of specific performance domain pursued and character of challenges confronted. As suggested by and consistent with the developmental psychology concept of the *sensitive period*, flexibility and reversibility are possible. The more significant and unfortunate conceptual issue is that the notion of recovery is too infrequently applied to ethnically diverse youngsters who are members of minority groups or, more generally, who grow up in families with few economic resources. Instead, as described and promoted, communicated are long-standing and entrenched sets of a priori assumptions concerning negative outcomes; subsequently, the images themselves may become translated into challenging contexts for self and others.

Specifically, frequently encountered are instances of devaluation perceived as stigma and stereotyping that require the individual's responsive coping. In fact, relative to resilient outcomes, Vander Zander (1985) suggests that recoveries from long-term effects due to short, traumatic episodes are possible. His conclusion stems from a review of classic resiliency findings and includes Werner's (Werner, 1989, 2000; Werner & Smith, 1982, 2001) longitudinal research efforts with Kauai youngsters and Jerome Kagan's (Kagan & Klein, 1973) observations and analysis of his work with Guatemalan children, along with inferences from similar studies by other developmental scientists conducting cross-cultural work.

We bring up the evident point that there continues to be some degree of difficulty or resistance to the introduction of alternative perspectives to account for the experiences of diverse American youth—particularly children of color—and immigrant youngsters. In our introduction of an alternative framework for explaining the “how” of human

development for diverse youth (see Spencer, 1995; Spencer & Harpalani, 2003), the intent was to explore human development theorizing that would be sensitive to the unique situations of American minorities specifically, although inclusive of diverse ethnicities more broadly. In fact, the introduction of PVEST was neither intended to foment theoretical controversy nor to create unnecessary complexity. The goal remains to provide a heuristic conceptual device that is inclusive of the broad array of human potential and experiences in diverse cultural contexts. In fact, our perspective is consistent with Alfred North Whitehead's notions concerning the role of new paradigms. He notes: "a clash of doctrines is not a disaster—it is an opportunity" (quoted in Vander Zander, 1985, p. 54).

We take the opportunity and use PVEST as a conceptual tool for broadening our understandings about vulnerability as experienced by diverse groups. The task entails the consideration of human vulnerability that requires the integration of both risks and protective factors; the latter also considers the role of privilege (generally an unacknowledged feature) as a salient protective factor. The inclusion has implications for our thinking about competence and resilience.

Recent theories that emphasize positive youth development, in fact, have infrequently afforded both a competence-exploring view (i.e., that also implicates the fact of privileging opportunities for a select group; see McIntosh, 1989) and a resilience-explaining perspective. Accordingly, PVEST introduces an alternative approach as an overdue option. As a systems theory, the framework provides a context-linked, nondeterministic (i.e., avoids unidirectional and pathologizing points of view), and culturally sensitive human development conceptual strategy. The specific caution for broad sensitivity, we believe, may represent the needs of cultural minorities, including diverse youth from low-resource families and those with a particular history, such as Native American people (Provenzo, 1986). Without doubt, these youth, too, pursue normative development goals of competence formation, albeit under challenging conditions (e.g., see Fuchs & Havighurst, 1972). In fact, as reported by Provenzo, Fuchs and Havighurst describe the failure of American education to adequately meet Native youths' need for competence:

With minor exceptions the history of Indian Education had been the transmission of white American education, little altered to the Indian children as a one-way process. The institution of the school is one that was imposed and controlled by the non-Indian society, its pedagogy and curriculum little changed for the Indian children, its goals primarily aimed at

removing the child from his aboriginal culture and assimilating him into the dominant white culture. Whether coercive or persuasive, this assimilationist goal of schooling has been minimally effective with Indian children, as indicated by their record of absenteeism, retardation, and high dropout rates. (Fuchs & Havighurst, 1972, p. 19 as reported by Provenzo, 1986, pp. 206–207)

According to Wenner (1972), often the value system communicated by the curriculum is at odds with group values and their expression. He suggests that a Hopi child may attempt to manifest the least (personal) effort as a way to diminish the embarrassment experienced by a less talented classmate. It is not that competence supported by effectance motivation does not exist. Conversely, individual-level expression takes second place to Indian customs; in the pursuit of competence outcomes, the latter places group accomplishments over personal achievement (Fuchs, 1986).

Competence Theorizing and Individual Vulnerability

As thoroughly reviewed elsewhere (e.g., Spencer, 1977, 1995), Robert White's (1959) theorizing, first published 50 years ago, suggested that the progression of human development is based on an *intrinsic motivation*; that is, humans possess an essentially biological propensity toward competence and effective interactions with the environment. White did not qualify his analysis based on race, ethnicity, social class, gender, faith group, immigration status, or national origin. As a term, competence suggests a state of "proficiency," "ability," "fitness," "adequacy," "capability," or "answering to all requirements"; he viewed this underlying "human propensity or drive" as the major source of the organism's motivation when interacting in multiple settings. The inference from White's analysis is that the individual wants to be effective; that is, one wishes to make a difference.

In their attempts to understand human motivation, other theorists have provided parallel perspectives. Foote and Cottrell's (1955) views suggest that competence is parallel with ability (i.e., as a satisfactory degree of ability for performing certain implied kinds of tasks). Similarly, deCharms's (1968) notion of personal causation continues the theme that the primary motivational propensity experienced by humans is to be successful in effecting change in their environment. Like White, DeCharms believes that the proclivity to make a difference is an intrinsic biological motivational goal. Considered collectively, their views suggest simultaneous and overlapping inputs from the

cognitive and affective domains as individuals socially engage the normative stage-specific tasks of human development (see Havighurst, 1953).

One of the important and positive aspects of S. Anderson and Messick's (1973) contribution to the discussion of competence is that they describe and clarify the broad range of both affective and cognitive dimensions included in the concept of competence. Their explicit detailing of both contributions supports analyses by traditional competence theorists and demonstrates associations between evolving social-cognitive processes and basic social and emotional development. That is, early development of self-other distinctions provides the opportunity for incorporating and understanding context interactions, including important self-inferences that often emanate from such interactions. Consistent with Flavell's (1968) early description of social-cognitive processes as linked to basic social and communication skills along with recent and progressively elegant fine-tuning of these inferential processes by theory of mind researchers such as Frye and More (1991) and Repacholi and Slaughter (2003), several outcomes are evident. Specifically, it is youths' early and progressive social-cognitive development that allows for the cognition-based awareness of others (i.e., their attitudes, beliefs, preferences, biases, and broad perspectives). The gradually unfolding process affords the recursive consideration of "the other" in the construction of the self and the establishment and experience of social-emotional development. Too frequently and unfortunately, theorizing focuses either on cognition or on affect, without relaying their psychological connectedness and unavoidable physiological interdependence. Given the reviews provided, it is evident that specifying these associations is of critical importance; their salience is associated with the varying character of context quality, particularly as linked to group membership and evaluative judgments, and individual differences in sensitivity to their impact.

As individuals transition across settings and produce behavioral products (i.e., coping outcomes as either reactive responses or identifications adopted), variously described by an array of attribution theorists, outcomes are comparatively evaluated. Accordingly, given the recursive character of linkages between levels of the ecosystem and unfolding human development capacities, the individual's unavoidable cognitive and affective processes (experienced both psychologically and physiologically) are associated with the socially constructed character of the context. Consequently, responsive coping will be required and competence or fragility outcomes produced and evaluated. As a recursive system, vulnerability is affected due to changes

in either risk level or protective factor level presence—thus continuing the cycle. As illustrated and described by Youngblood and Spencer (2002) regarding educational considerations needed for special needs populations and the goals behind Individuals with Disabilities Education Act (IDEA) legislation, we surmise that independent of assumed need level, supporting the basic intrinsic need for competence should be a core aspect of all inclusive programming. In general, then, when considering the entire life course and stage-specific outcomes from a PVEST systems perspective, a foundationally important and productive coping outcome expected (independent of developmental status, inferred level of support available, or special assistance required) is the acquisition of an array of stage-specific competencies.

Competence generally refers to being robust, healthy, and proficient. As suggested by White's (1959, 1960) earliest essays on the topic, he "urged the relevance to human development of an intrinsic motivation toward competence—toward effective interaction with the environment" (as reported by Fisk & Maddi, 1961, and reviewed by Spencer, 1977). Relatedly, Robert Havighurst's (1953) analysis of human development describes sets of normative tasks that are linked with the several developmental periods and represent the several core domains of human functioning (i.e., social, cognitive, affective, and physical). For each period, mastery of a stage-specific skill set is required for general competence and the successful transition through the current stage and, ultimately, for achieving positive developmental stage-specific outcomes: that is, *demonstrations of competence*.

Competence theorists such as White (1959, 1960) have been insightful in their multidimensional perspectives concerning competence formation. As described earlier, the pursuit of competence is a highly regarded achievement outcome professed by society, lauded by schools, and valued by families. However, literatures indicate that the actual "practiced view" about competence formation is, at best, narrowly applied and monolithic in character. As suggested elsewhere (see Spencer, 1977), when one notes the goals of education and then assesses the outcomes, Edmund Gordon's comments are insightful:

Although the goals of education tend to be stated in broad terms, when we come to assess education it is always to cognitive development and achievement that we first look for evidence of change. Too often we either stop with these first results or turn with less rigor to look at other areas as a second thought or as a rationalization for failure to find more impressive evidence in the cognitive domain. (quoted in S. Anderson & Messick, 1973, p. 3)

As suggested by Spencer (1977), the outcome of the approach is an inadequate or shortsighted understanding about how individuals come to function as competent members of society. Alternatively, our approach has been to respond to Gordon's long-term admonishment by addressing simultaneously the multiple domains of human development as linked to personal and group demographics along with context features. Spencer's review and synthesis of competence formation theory cites Smith's (1968, p. 272) query, which remains generally unaddressed and, thus, still holds sway today:

What do we know, and what do we need to know about the conditions under which people come to function as competent members of society? The question arises with urgency as the first generation of crash programs to instill competence in the poor and "culturally deprived" comes under skeptical review, and the path to the millennium remains to be discovered.

We are nearly 40 years past Smith's prescient pronouncement and are 5 years into a new millennium. Unfortunately, there appears to be no closer commitment to broad, multiple domain-relevant analyses of youths' competence formation processes for use in the design and structuring of culture-, context-, and development-sensitive educational systems and intervention/prevention programming strategies and more general practices.

It is important to note that not all efforts expended in pursuit of competence formation are equally rewarded. That is, the environment presents different levels of challenge as well as provides varying levels of supports and privileges. Of special salience, although not frequently acknowledged, is that the hurdles confronted are not independent of individual group members' characteristics (e.g., race, ethnicity, socioeconomic or immigration status, faith group) along with the group's hierarchical placement in American society. Consequently, resilience (i.e., successful effects achieved in the face of challenge) may not always be the outcome. In fact, although originally queried virtually 40 years ago by competence theorists in the mid- to late 1960s, lingering inferred questions remain: How much challenge is motivating for resilient results and stage-specific competencies? On the other hand, how much challenge (given a lack of equivalent, culturally sensitive, customized, and specific support) is undermining of potential competence accrual and resiliency?

CONCLUSIONS AND FUTURE DIRECTIONS

Infrequently explored perspectives provided by this review and synthesis, we believe, afford significant insights for

conceptualizing the literature to date. The alternative analyses not only make available helpful conceptual devices but suggest important directions for future research, programming designs, evaluation efforts, and theorizing about intra- and interindividual developmental processes. For example, differential supports are provided and individuals' efforts expended in pursuit of stage-specific competencies as dictated by the normative developmental tasks originally described by Havighurst (1953). That is, although neither formally acknowledged nor openly discussed in the developmental literature, in general, for the diverse groups considered, our review indicates particularly patterned individual-context relationships. They are of relevance for resilience theorizing and suggest the multiple domains of human competence. More to the point, there appears to be specific linkages between the hierarchically organized American social structure and youths' experiences of excessive challenges versus available supports. In fact, the social arrangements translate into at least two patterns. In one case, persistent impediments encountered as one transitions across time and place potentially interfere with the assembly of competent outcomes; on the other hand, and as suggested by McIntosh (1989), particular individuals may experience subtle sets of generally unacknowledged and highly ego-boosting privileges. The differences are important for the allotment of resources and future expectations for human capital investments. That is, they impact current and future planning.

It is important to acknowledge that frequently ignored are the ethnicity-linked mismatches for individual and context associations and, on the other hand, the privileging experiences of particular youth. The long-term and failed appreciation of the dilemma (1) tends to generate significant levels of "social uncomfortableness"; (2) connotes and spawns continuing social inequities; (3) generates, on occasion, heated denials; (4) through stigma and stereotyping spawns experiences of "stereotype threat"; or (5) invokes an "official" policy-relevant response of "motivated forgetfulness." The last is especially perplexing because diverse youth routinely appear on textbook covers, are included in textbook pages, and generate voluminous submissions as research proposals in response to requests for applications, which, too frequently, provide inadequate diversity of ethnic representation in the decision-making ranks of review and oversight teams. Salient for future directions, remaining unaddressed is the reality that differential treatment only further exaggerates the noted lack of fit for some and appearances of broad success for others. Patterns of excessive social impediments are apparent, as experienced particularly by visible and disfavored minority

group members (see Chestang, 1972a); on the other hand, also present are demonstrations of conspicuous consonance and supports experienced by others as White privilege (McIntosh, 1989). Laws may be viewed as a source of legal protection for all citizens. Unfortunately, socially structured impediments as social practices are not independent of race, ethnicity, immigration status, gender, religious faith, skin color, and social class; nor are they always easily discernible, although their psychological impact is severe (see Chestang, 1972a, 1972b). The issues of visibility, identifiability, and stigma are important because they represent an individual's recognition of devaluation and difference; the discernment has implications for competence and effectance motivation. A review by Spencer, Kim, and Marshall (1987) describes the experiences of an underperforming outcaste minority of Japan (i.e., Buraka youth) and analyzes the youths' subsequent high-performance experiences in the United States, where they are treated as valued (i.e., "model minority") group members. The cross-national work reviewed by Spencer, Kim, and Marshall suggest the importance of the individual-context match (i.e., consonance) or mismatch (i.e., dissonance producing). Of particular importance, the degree of fit suggests experiences of privilege versus persistent (although generally unacknowledged) inequality.

The burgeoning Whiteness studies engineered by legal scholars (e.g., Bonilla-Silva, 1997, 2001) are insightful in their analyses of the myriad ways through which privilege is bestowed and enjoyed; similarly, the more general exploration of privilege by McIntosh (1989) and Luthar (Luthar & Becker, 2002; Luthar & Latendresse, 2002) has made critically important contributions. Structured impediments that emanate from a hierarchically organized social system are hypothesized as contributing an impact. As obstructions, however, they are experienced by youth as cultural dissonance accrued as a function of a lack of fit between one's cultural distinctiveness and the character of responses from particular contexts (see Spencer, 1999, 2001). Youths' responses to the degree of individual-context fit may result in consequent challenges; adequate counteracting supports are required for offsetting their effects and for limiting overall stress. Their consideration has future implications for resource needs and their planned distribution.

On the other hand, and infrequently addressed, we can infer the need to deploy adaptive coping strategies that are minimally consequential for the individual (e.g., use of an economic privilege such as a "legacy admission" standard as opposed to choosing not to pursue postsecondary education or opting for a less prestigious college). Without sup-

ports, maladaptive reactive coping responses adopted, such as declining postsecondary educational options, may have dire consequences for identity processes and long-term stage-specific coping outcomes, such as the maximization of earning potential. Inevitably, although generally overlooked, the frequent and unquestioned use of available privileges may result in the failure to hone adaptive options as reactive coping strategies in response to normative and atypical challenges. Information garnered in the aftermath of the Columbine High School massacre along with other untoward occurrences aids in exploring questions concerning the frequently unacknowledged downside of privilege.

Persistent exposure to atypical levels of patterned obstacles or, on the other hand, to collective experiences of noticeable nonappearance of typical challenges may result in inauthentic self-constructions and difficult affective processes. A general example is inaccurate assessments of self-attributions and personal characteristics that inadequately link inferred effort with coping outcomes. Thus, on the one hand, examples of the former (i.e., atypical levels of patterned obstacles) may suggest inauthentic self-constructions concerning ability or performance potential if one is confronted with too much challenge (e.g., inability inferred given confrontations with unacknowledged negative stereotyping). On the other hand, significant unacknowledged supports and few obstacles might suggest an inauthentic self-construction of ability (i.e., exaggerated intellectual or social prowess, suggesting beliefs of "earned" status).

The former situation (i.e., atypically highly challenging contexts), even if accompanied with significant supports, may result in coping skill development and positive coping products that define and explain resiliency (i.e., positive outcomes in the face of significant challenge). Without adequate supports, on the other hand, we can expect the successful adoption of maladaptive psychological coping skills that provide an identity of short-term salience although accompanied by less than viable long-term identifications and productive coping outcomes.

In the latter situation (i.e., noticeable nonappearance of typical challenge), its accompaniment with unacknowledged and significant levels of support results in specific outcomes: a consequent state of privilege and psychosocial disconnectedness. Associated characteristics include narrowly developed social connectedness; rugged independence; limited, underdeveloped, and narrow sense of interdependence; and inadequate sense of responsibility (i.e., beyond the self). This suggests a failure to acknowledge and internalize social connectedness and sense of responsibility. We hypothesize, as a consequence, a level of personal psychosocial

inauthenticity (i.e., overestimation of self), psychological fragility (i.e., lack of honed adaptive coping skill development), and societal inconsistency (i.e., lack of social connectedness or sense of interdependence).

We hypothesize that the perceptual processes involved and reinforced are intergenerationally transmitted and observed both within and between groups (particularly when comparisons are made with White, male, privileged group members). As described, characteristics such as social class, immigration status, English-language proficiency, and skin color may aid the analysis of within- and between-group differences because dissonance is often linked with stereotyping and stigma; the latter, unfortunately, is frequently coupled with membership in a particular identifiable group. The outcomes produced given problematic individual-context matches contribute to additional risks and increased vulnerability; the latter is experienced as challenging conditions that require reactive coping responses by individuals given the developmental tasks confronted at that particular life course placement. Their repeated usage becomes internalized as emergent identities that, without supportive feedback and interventions (for good or bad reasons), may remain manifest across time and place.

For example, Spencer's plan of research in response to Clark and Clark's (1939, 1940) investigations was initiated in the early and middle 1970s and, for the most part, first published in the early 1980s (Spencer, 1982a, 1982b, 1983, 1984; Spencer & Horowitz, 1973). At the time, it was generally assumed that Black children's early Eurocentricity (i.e., White preference responses when queried about racial attitudes, values, preferences, and beliefs suggested high vulnerability—in fact, self-hatred; see Kardinier & Ovesey, 1951; Pettigrew, 1964). Spencer's program of research indicated significant mediating and previously unacknowledged developmental processes: Specifically, the findings were interpreted by Spencer as indicating that children's early and cognition-based egocentrism served to protect ego functioning and from inferring negative stereotypes and internalizing negative affect. Additionally, particularly with middle childhood youths, parents' cultural socialization efforts were found to matter in offsetting the potential negative impact of Eurocentric attitudes and color bias experienced as social stereotypes about racial group membership (see Spencer, 1983, 1990; Spencer & Dornbusch, 1990; Spencer & Markstrom-Adams, 1990); more recent research efforts by H. C. Stevenson (1994, 1997) and colleagues (Arrington, 2002) further validate the assumption. Accordingly, from a future directions perspective, it is evident that new conceptual strategies for thinking about resiliency prediction and broad ego func-

tioning are needed both for youth of color and Whites. When the program of research by Spencer is scrutinized along with recent Whiteness studies (e.g., Haney-Lopez, 1996; Ignatiev, 1995) and McIntosh's analysis of White privilege (see Luthar & Becker, 2002; McIntosh, 1989), the combined perspectives afford broad, innovative, and analytic formulations; of particular importance, the synthesis suggests new criteria for the definition of resilience. As described by Spencer and Swanson (2000), we need frameworks that explain the variations in the character of youths' life course transition (i.e., toward increased vulnerability or the achievement of resilience). Illustrated as a dual-axis formulation of PVEST in Figure 16.3, we infer that significant variations in the experience and prediction of resilience exist. The often patterned variability represents the character of youths' transitions across multiple ecological contexts, as influenced by social structures made manifest through particular experiences in schools, families, peer networks, and neighborhoods.

Anne-Marie Ambert's (1997, p. 41) analysis provides conceptual balance and suggests that "a percentage of adolescents do cause a great deal of problems for parents, society and themselves. They consequently receive media coverage and attention from professionals." The Columbine massacre and many urban homicides are reminiscent of Ambert's analysis. However, as described by Spencer and Swanson (2000), many young people manage to engage in productive coping and to make their way through childhood

		Risk Factor <i>Level</i>	
		High	Low
Protective Factor <i>Presence/Experience</i>	Low (not evident)	Special Needs Evident: Quadrant I (highly vulnerable)	Symptoms Not Evident/ or Overlooked: Quadrant II ("masked" vulnerability)
	High (significant presence)	Resilience Expected: Quadrant III (low vulnerability)	Untested: Quadrant IV (undetermined vulnerability)

Figure 16.3 PVEST Dual Axis Coping Formulation. PVEST-linked Vulnerability Level and Resiliency Dual Axis Model (M. B. Spencer, 2004; in press). Adapted from "Introduction: The Syndrome of the Psychologically Vulnerable Child," by E. J. Anthony, in E. J. Anthony and C. Koupernik (Eds.), *The Child in His Family: Children at Psychiatric Risk*, 1974, New York: John Wiley & Sons, Inc.

and adolescence without much disruption and do not receive much publicity. As resilient young people, such youth grow up with an authentic sense of self and cultural connectedness (i.e., sense of cultural pluralism, defined as the valuing of one's own cultural niche although also respecting the cultural uniqueness of others), social equity, healthy ego functioning, and a sense of social justice.

In fact, the dual-axis formulation of PVEST shown in Figure 16.3 suggests the possibility of determining who is vulnerable or not and describing the conditions and variability of support available to them. Four quadrants of youth are depicted in the PVEST dual-axis coping formulation (typically, only two groups of youngsters are referred to in the literature). Quadrant I represents highly vulnerable young people who have particular and special needs. Considered in the literature that includes diverse youth, Quadrant I individuals have special needs and too frequently are inferred to be either minority, pathological, impoverished, or problem burdened. The reasons for their challenges are generally thought to reside within the individual. They are usually listed in texts as highly vulnerable due to multiple risk factors assumed to be of their own creation (e.g., genetic predisposition, social class, temperament, or a physical or neurological malady).

The second most frequently referred to group, Quadrant IV, comprises everyone else who is doing well and is generally assumed to be White, middle income, and up until the mid-1970s narrowly conceived of as males. These youth are presented as the standard against which everyone else is judged. More specifically, these individuals are generally those demonstrating positive stage-specific outcomes when considered from the cradle to the coffin. Quadrant IV individuals are represented as the norm for evaluating the degree of atypicality of Quadrant I individuals. Stated differently, individuals who experience low levels of risk and enjoy the significant presence of protective factors are heralded as the standard of competence utilized for comparison with all.

However, our literature review suggests that there are at least two other groups of underacknowledged individuals. The first, Quadrant II, are those who have both *low risks and low levels of protective factors* (e.g., demographics of the Columbine High School killers, who enjoyed low risks given affluence and safe neighborhoods but lacked close parental monitoring and social connectedness). These students are seldom carefully scrutinized by socializing adults, given the apparent absence of stereotypic risk factors; in fact, the lack of external scrutiny and lack of supported and positive coping opportunities and history tends to increase their fragility and vulnerability in the face of

acute challenge. The emotional pain associated with acute and often normative challenge, with the lack of honed coping skills and positive adaptive coping strategies, results in the use of maladaptive coping strategies (e.g., mass murders or deviant organization memberships, i.e., Aryan Brotherhood, skinhead societies). Their various behavioral outcomes may not warrant significant attention; they are thus left to their own coping devices and are assumed to be healthy (i.e., their fragility is ignored).

Quadrant III individuals are infrequently the focus of media attention. They are represented by high risks but also have access to and make use of significant protective factors (e.g., high parental monitoring; supportive and available socializing adults; good adaptive coping skill development and use; and salient identifications, i.e., with faith groups, national identities, reference group orientation). We hypothesize that Quadrant III youth are the truly resilient individuals because they habitually demonstrate good and productive outcomes in the face of persistent challenge. For example, work by Spencer and colleagues suggest that parental monitoring matters (e.g., Spencer, Dupree, Swanson, & Cunningham, 1996; Spencer & Swanson, 2000), identity processes are supportive (Spencer, Cunningham, & Swanson, 1995), and neighborhood and family influences make a difference (e.g., Spencer, Cole, Jones, & Swanson, 1997). It is apparent from our dual-axis formulation of PVEST that we know the least about Quadrants II and III. Further, what we assume about Quadrant IV is inadequate because, if considered closely, these youth are untested relative to resiliency presence or absence. If they are actually Quadrant II youth, the mislabeling is important, as opportunities are being missed for providing greater support. For determining their resilience, different research questions will need to be asked because their current positioning suggests inordinately high levels of privilege versus true resiliency. Alternative queries of Quadrant IV should include exploration of identifications that suggest connectedness to others as opposed to a dependence on available supports and an absence of obvious challenge. For Quadrant III, it will be important to understand variability even within this group. That is, as noted previously, given the presence of high risk, how much risk can be handled with traditional supports, and how much risk (and its character) requires equivalent levels of significant supports?

In this chapter, we attempted to detail the myriad challenges experienced by diverse youth and the unique sources of support. We suggest that human vulnerability represents the combination of risk level balanced against protective factors. It is evident that for some youth, there continues to be a significant focus on risks without equivalent analysis

of protective factors and their translation into supports that differ for the many groups. For other groups, assumptions of privilege mask our potential understanding of youthful risk as a function of significant support and, for many, unacknowledged privilege. An understanding of all four quadrants of the dual-axis formulation of PVEST is required for designing contexts for maximizing resilient outcomes for all youth. Consistent with theorizing by Robert White, the characterizing of behavioral outcomes as resilient is not possible without a full understanding of challenge, both stage-specific types with normative confrontations and the acute and atypical varieties. The insights have implications for future directions in that they aid the design of supportive programming and policies to assist in obtaining authentic resilient outcomes for youth more generally. This can occur, for some, through providing customized supports for decreasing vulnerability through risk factor reduction. For those who enjoy unacknowledged privilege and infrequent authentic challenge, identity interventions that promote social connectedness and acknowledgment of mutual responsibility may be the type of interventions required.

We submit that the PVEST provides specific implications for future and policy directions needed for diverse communities of children and families. As a process-oriented and systems framework that enhances the interpretation of diverse expressions of human development, including the etiology and character of human vulnerability, it should fine-tune future planning for specific groups' needs. As a context-linked, history-relevant, and culturally sensitive framework, it allows for the customization of strategies and supports for diverse groups, while intended for accomplishing the same outcome for all: resilient outcomes in the pursuit of competence and effectance motivation.

Summary	690
Directions for Future Research	690
Linkages between Probabilistic Epigenesis and Prevention and Resilience	693
CONCLUSION	695
REFERENCES	695

The developmental mode of analysis is the only method that can truly explain the structures and functions of maturing and mature organisms. This is an insight that dates back to the resolution of the epigenesis-preformation debate in the 1700s. The crux of the notion of developmental analysis was succinctly stated by Caspar Friedrich Wolff in his great treatise on embryological development of the chick: “. . . each part is first of all an effect of the preceding part, and itself becomes the cause of the following part” (Wolff, 1764, p. 211, cited in Hall, 1999, p. 112). The singularly important role of developmental analysis took a great leap forward in the late 1800s with the establishment of experimental embryology by Wilhelm Roux (reviewed in Gottlieb, 2002c), in which normal development was systematically perturbed to get an understanding of what was called the “mechanics of development” (*Entwicklungsmechanik*). The latter term was used by Roux to describe a new science of causal morphology, that is, an investigation of the development of form, not the mode of action of an already formed mechanism (reviewed in detail by Russell, 1917).

For the present purposes, the results of the various experimental manipulations of the embryo and its developmental

context are of extreme importance. The various manipulations of the early embryo typically caused different outcomes of development, thus giving rise to two significant metatheoretical concepts: *reaction potential* and *interaction*. Reaction potential referred to the heredity of the organism, bits and pieces of which were revealed depending upon the specific interactive influences that were allowed, or made experimentally, to operate during embryonic development. Today in developmental biology, the term *epigenetics* has come to refer to “the control of gene expression by the environments and microenvironments encountered by embryos or parts of embryos . . .” (Hall, 1999, pp. 113–114). So, in developmental biology, the ubiquity of interaction is taken for granted and extends to the activation of genetic activity by nongenetic influences, not just the formative influences of cell-cell, tissue-tissue, and organ-organ interactions. It makes good sense to extend this point of view to developmental psychology, and, with some added refinements, that is what the first author has been attempting to do with the metatheoretical model called *probabilistic epigenesis*.

PROBABILISTIC EPIGENESIS

Probabilistic epigenesis is to be contrasted with predetermined epigenesis, the latter holding that genetic activity gives rise to neural (and other) structures that begin to function when they become mature in the unidirectional sense of genetic activity → structure → function. In contrast, in line

The first author’s contribution to the preparation of this chapter was supported by National Institutes of Health Grant MH-52429 and National Sciences Foundation Grant BCS-0126475. A portion of the introductory material to probabilistic epigenesis was adapted from an article by the first author that appeared in *Human Development*, volume 46, 2003.

with the evidence now available at all levels of analysis, probabilistic epigenesis holds that there are bidirectional influences within and between levels of analysis so that the appropriate formula for developmental analysis becomes genetic activity \leftrightarrow unction. In this view, neural (and other structures) begin to function before they are fully mature, and this activity, whether intrinsically derived (“spontaneous”) or extrinsically stimulated (evoked), plays a significant role in the maturation process. This principle of the probabilistic epigenesis of neural development was enunciated by Gottlieb (1971), and its importance is only intermittently recognized in neuroscience. One of the exceptions is the following quotation:

... much current theorizing on the neural basis of sensory, motor, and cognitive development is based on a viewpoint in which the maturation of particular neocortical regions allows or enables new functions to appear. This is clearly based on a predetermined epigenesis viewpoint in which the primary cause of a cognitive change can be attributed to neural maturation. A number of recent reviews of pre- and postnatal brain development have concluded that probabilistic epigenesis is a more appropriate way to view postnatal brain development (e.g., Johnson, 1997; Nelson & Bloom, 1997). Explaining developmental change when there are bi-directional interactions between brain structure and (psychological) function is far more challenging than the maturation view. When adopting a probabilistic-epigenesis viewpoint, the aim remains to unite developmental neuroanatomical observations with functional development. However, a probabilistic-epigenesis approach emphasizes the need for notions of the *partial functioning* of neural pathways. This is because, in order for bi-directional interactions between brain structure and function to work, there needs to be early partial functioning which then shapes subsequent structural developments. The cortical regions are not silent before they abruptly become activated in their mature state. Rather, structural and functional changes in regions of the brain co-develop. (Johnson, Halit, Grice, & Karmiloff-Smith, 2002, pp. 525–526)

Because the coordination of formative functional and structural influences within and between all levels of analysis is not perfect, a probabilistic element is introduced in all developing systems and their outcomes. The fully sketched model, including behavior and extra-organismic environmental influences, is shown in Figure 17.1.

The biggest obstacles in getting the probabilistic-epigenetic model understood and accepted by biologists, neuroscientists, and social scientists concerns (1) its view of the role of genes in the developmental process; (2) implementing the probabilistic-epigenetic framework in ongoing research, including the reciprocity (bidirectionality) of influences

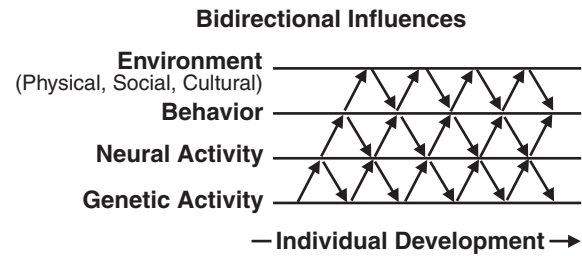

Figure 17.1 Metatheoretical model of probabilistic epigenesis: Completely bidirectional influences over four levels of analysis (genetic activity, neural activity, behavior, physical, social, cultural aspects of environment). *Source:* From “Emergence of the Developmental Manifold Concept from an Epigenetic Analysis of Instinctive Behavior” (pp. 31–56), by G. Gottlieb, in D. Lewkowicz and R. Lickliter (Eds.), *Conceptions of Development: Lessons from the Laboratory*, 2002a, New York: Psychology Press. Reprinted with permission.

within and between the four levels of analysis (genetic activity, neural activity, behavior, and the physical, social, and cultural influences of the external environment); and (3) a seemingly unorthodox take on the concept of interaction, particularly the ubiquity of gene-environment interaction. There is some necessary overlap in these three issues, but we will discuss them in turn.

Role of Genes in the Developmental Process

The fact that DNA is an inert molecule means that genes can’t turn themselves on and off; they require intracellular signals, some of which originate from outside the cell and, indeed, outside the organism. The claim of the central dogma of molecular biology is that proteins are made by the predetermined unidirectional formula DNA \rightarrow RNA \rightarrow protein, in which case the genes would be pictured as the unmoved movers of development. (The DNA \rightarrow RNA relation is called transcription and the RNA \rightarrow protein relation is called translation.) The truth of the matter is that proteins can and do act on RNA and on DNA, and that in the most dramatic case RNA can transform DNA by a process called reverse transcription. Genes are composed of units called exons (the coding units) and introns (noncoding units). In order for RNA to make protein the introns must be “edited” out by a process called alternative splicing. In alternative splicing there is a reshuffling of the RNA transcription of a gene’s nucleotide sequence that generates multiple proteins from the same originating gene. This is accomplished by *spliceosomes*, a specialized group of proteins and ribonucleic acids (RNAs) that not only edits out the introns but can add exons to the transcript! That is how the same gene

can be associated with more than one protein. Proteins are what become nerve cells, liver cells, skin cells, muscle cells, and so on, so the development of the structure and function of proteins studied by those involved in *proteomics* is heralded as the next big step in our understanding of genetic activity in the developmental process: “Its [proteome analysis] ability to confirm the existence of gene-products predicted from DNA sequence is a major contribution to genome science” (Humphrey-Smith, Cordwell, & Blackstock, 1977, p. 1217). In terms of attempting to correlate genes with developmental outcomes at the neural and behavioral levels, we need to constantly remind ourselves of the uncertainty involved. Because much of the genetic analysis in humans involves single nucleotide polymorphisms (SNPs), which are merely markers for as yet unidentified genes, RNA editing adds a further complication in trying to specify the involvement of specific genes in neural and behavioral outcomes. One human gene may produce up to five different proteins as a result of alternative splicing (Peters & Boekholdt, 2002).

The search for SNPs has proceeded apace; so far, 3 million of them have been identified and mapped in the human genome, and “these represent only a fraction of the SNPs present in the human genome as a whole” (Venter et al., 2001, p. 1346). Given that there are now considered to be only 26,000 to 38,000 genes in the human genome, the number of SNPs is startling and indicates the arduousness of the task of identifying individual genes or gene complexes, and this complexity comes on top of the problem of alternative splicing. These problems notwithstanding, the scientific program of attempting to correlate genes with neural and behavioral outcomes pushes on using polymorphisms as the stand-in for genes. We have no quarrel with this pursuit, but only wish to alert those readers who may be unfamiliar with the enormity of the problem of actually identifying genes that are involved in the neural and behavioral developmental process of humans. Along with Carolyn T. Halpern, the first author himself is engaged in such a pursuit in collaboration with a geneticist, Trudy Mackay.

We believe it is essential to adopt a probabilistic-epigenetic framework in attempting to correlate genes (and their markers) with neural and behavioral outcomes. The reason this is necessary is that genes are not exempt from influences at other levels of analysis but are, in fact, dependent upon them for initiating and terminating their activity. And when we say “probabilistic-epigenetic framework,” we do not mean merely the DNA \leftrightarrow RNA \leftrightarrow protein level of analysis but the other three levels as well. There is considerable evidence that genetic activity is influenced by neu-

ral, behavioral, and external environmental events, and the results of a number of those studies are summarized in Table 17.1.

The failure to replicate genetic studies of psychopathology, as well as genetic \rightarrow neural outcomes, is legion, and we think those numerous failures should be taken as a datum. For example, in reviewing more than 200 studies of the involvement of polymorphisms in dopamine receptors, the latter known to be involved in a number of disorders, Wong, Buckle, and Van Tol (2000, p. 194) came to these conclusions:

The myriad, conflicting results of association and family linkage studies cannot be easily summarized. There is essentially no clear-cut case in which polymorphisms in any of the dopamine receptor genes are related to neuropsychiatric disorders, or even to a specific phenotype. . . . This uncertain picture is not unique to the pharmacogenetics of dopamine receptors, as a similarly confusing scenario is found in many complex genetic diseases, including some that have been discussed in the review such as Schizophrenia and bipolar disorder.

The fundamental issue may be that dopamine receptors are only one component of the array of neurotransmitter receptor systems that influence behavior in concert with genes that control neurodevelopment, connectivity, neuronal signaling, and synaptic plasticity.

We think this strictly unidirectional, bottom-up approach advocated by the authors in the second paragraph of their quote, though prevalent in this area of study, will not solve the problem: The recognition of the bidirectionality of influences and the involvement of the behavioral and environmental levels of analysis will have to be included in order to successfully link genes and nervous system to developmental-psychopathological outcomes. If this more comprehensive analytic framework is not implemented, we believe there will be continued failures of replication between genotypes and neural and behavioral outcomes, whether psychopathological or otherwise.

Implementing the Probabilistic-Epigenetic Framework

Given the present state of the art and science of the various disciplines involved, implementing the probabilistic-epigenetic framework will necessarily be a piecemeal affair. We have not only the four levels of analysis to deal with but the reciprocity (bidirectionality of influence) among them. We need to be opportunistic in seeking out transdisciplinary collaborations and taking advantage of those that present themselves. We will here document that where it has been

TABLE 17.1 Normally Occurring Environmental and Behavioral Influences on Gene Activity

Species	Environmental Signal or Stimulus	Resulting Alteration
Nematodes	Absence or presence of food	Diminished or enhanced neuronal <i>daf-7</i> gene mRNA expression, inhibiting or provoking larval development
Fruit flies	Transient elevated heat stress during larval development	Presence of proteins produced by heat shock and thermotolerance (enhanced thermal regulation)
Fruit flies	Light-dark cycle	Presence of PER and TIM protein expression and circadian rhythms
Various reptiles	Incubation temperature	Sex determination
Songbirds (canaries, zebra finches)	Conspecific song	Increased forebrain mRNA
Hamsters	Light-dark cycle	Increased pituitary hormone mRNA and reproductive behavior
Mice	Acoustic stimulation	Enhanced <i>c-fos</i> expression, neuronal activity, and organization of the auditory system
Mice	Light-dark cycle	<i>c-fos</i> -induced mRNA expression in hypothalamus, circadian locomotor activity
Rats	Tactile stimulation	Enhanced <i>c-fos</i> expression and increased number of somatosensory (sense of touch) cortical neurons
Rats	Learning task involving vestibular (balance) system	Change in nuclear RNA base ratios in vestibular nerve cells
Rats	Visual stimulation	Increased RNA and protein synthesis in visual cortex
Rats	Environmental complexity	Increased brain RNA diversity
Rats	Prenatal nutrition	Increase in cerebral DNA (increased number of brain cells)
Rats	Infantile handling; separation from mother	Increased hypothalamic mRNAs for corticotropin-releasing hormone throughout life
Cats	Visual stimulation	Increased visual cortex RNA complexity (diversity)
Humans	Academic examinations taken by medical students (psychological stress)	Reduced mRNA activity in interleukin 2 receptor (immune system response)

Notes: mRNA = messenger RNA; PER and TIM are proteins arising from *per* (period) and *tim* (timeless) gene activity; activity of *c-fos* genes leads to production of c-FOS protein. References documenting the findings listed can be found in Gottlieb (1998, Table 2).

possible to implement the probabilistic-epigenetic framework, even in a piecemeal fashion, the results have been promising. We will first provide the structure of how we envision the research enterprise that attempts to link genes to neural and behavioral outcomes.

We take it as a given that genes, in and of themselves, cannot produce any neural or behavioral outcome and that gene-environment interaction is a requirement of normal as well as abnormal development. (We critically discuss the thorny issue of the statistical concept of gene-environment interaction in the next section.) Thus, our probabilistic-epigenetic model of developmental outcomes assumes that individuals of the same genotype can have different neural and behavioral outcomes according to the *dissimilarity* of their relevant life experiences, broadly construed. We think this is the basis for the lack of replications among studies that look only at genotypes and attempt to correlate a par-

ticular genotype with a certain neural or behavioral outcome without looking for the presence or absence of intervening life experiences that may be crucial to the presence or absence of the outcome. Take the much-studied inhibitory neurotransmitter serotonin. Low levels of serotonin are associated with depression and alcohol abuse in humans. However, correlates of low serotonin are not behaviorally specific (i.e., low serotonin is involved in a number of psychiatric disorders). In rhesus monkeys, low concentrations of serotonin metabolites (collected from cerebral spinal fluid) are associated with higher levels of impulsive aggression and risk taking (e.g., taking long leaps: Suomi, 2000). Rhesus infants who develop the least secure attachment with their mother are also the most likely to have deficits in their central serotonin metabolism. Because there is a positive correlation between maternal and infant serotonin level, a genetic deficit could be involved, but it is

possible that aberrant maternal care may make a necessary contribution to the serotonin deficit. To shed light on the genetic and interactive aspect, Bennett et al. (2002) genotyped the monkeys in Suomi's laboratory for a known polymorphism (long and short allele) in the serotonin transporter gene (5-HTT). The short allele confers low transcriptional efficiency to the 5-HTT gene promoter (relative to the long allele), so low 5-HTT expression may result in lower serotonergic function. However, evidence for this in humans is inconsistent because the necessary life experience correlates have not been examined. In the case of rhesus monkeys, when attempting to correlate the genetic polymorphism to serotonin metabolism, serotonin concentration did not differ as a function of long or short 5-HTT status for mother-reared monkeys, whereas, among peer-reared monkeys, individuals with the short allele had significantly lower serotonin concentrations than those with the long allele (Bennett et al., 2002). Thus, the lowered serotonin metabolism was not simply a consequence of having the short allele but required the life experience of peer rearing in this instance. This result supports our idea that the inconsistencies in the human literature are likely due to unknown but influential differences in the experiential histories of the populations under study.

Thus, the notion that the short allele of the 5-HTT gene is inevitably associated with a central nervous system deficit or defect is not true: The neural outcome depends on the developmental rearing history of the animal, as well as the particular genotype of the animal itself, what has elsewhere been termed "relational causality" (Gottlieb & Halpern, 2002). The present finding most likely also explains why there are inconsistencies in the human literature in finding anxiety-, depression-, and aggression-related personality traits associated with variations in the serotonin transporter gene (inconsistencies are reviewed in Bennett et al., 2002). The association, or lack thereof, reflects not simply genetic causality but developmental-relational causality.

Turning to a similar example concerning the development of psychopathological behavior, a functional polymorphism in the promoter of the monoamine oxidase A (MAOA) gene is or is not associated with Conduct Disorder, violent offenses, disposition toward violence, and Antisocial Personality Disorder, depending on whether or not the adult person was maltreated in childhood (Caspi et al., 2002). Once again, because of the failure to recognize the generality of the necessity of gene-environment interactions in producing outcomes, "Evidence for an association between MAOA and aggressive behavior in the human general population remains inconclusive" (p. 851).

It is thought that the short form of the MAOA polymorphism, resulting in lower production of the MAOA enzyme that metabolizes neurotransmitters such as norepinephrine, serotonin, and dopamine, would make a person more prone to aggressive behavior than possessing the long form of the polymorphism. This inference comes from mouse studies in which the gene encoding MAOA is deleted and aggression is increased, whereas aggression is normalized by restoring MAOA expression.

The results of the Caspi et al. (2002) study support the present model of probabilistic epigenesis in that, when the children with the short form of the MAOA polymorphism are reared under conditions of no maltreatment, probable maltreatment, or severe maltreatment, it is only the latter group in which a substantial number (85%) exhibit some form of the four aggression measures listed above. Alternatively, having the long form of the genotype ("high MAOA activity") significantly reduces the probability of the development of antisocial behavior even under conditions of severe maltreatment.

This study shows very clearly that a knowledge of genotype and the presence or absence of an influential life experience provide indispensable aids to understanding the likelihood of an antisocial outcome in the face of maltreatment in childhood. This is another good example of relational causality, as well as the value of the piecemeal implementation of the probabilistic-epigenetic framework. Much remains to be done, but it is a valuable first step. As the authors themselves say, "Maltreatment studies may benefit from ascertaining genotypes associated with sensitivity to stress, and the known functional properties of MAOA may point toward hypotheses, based on neurotransmitter system development, about how stressful experiences are converted into antisocial behavior toward others in some, but not all, victims of maltreatment" (Caspi et al., 2002, p. 853). The probabilistic aspect is represented by the 85% figure ("some, but not all").

Another important aspect of implementing the probabilistic-epigenetic model is being alert to the reciprocity or bidirectionality of influences within and between the four primary levels of analysis in Figure 17.1. The documentation of bidirectionality is much easier in animal research than in human research because of the possibility of doing the necessary experimental manipulations in animals. Nonetheless, reciprocity has been observed across three levels in some developmental-psychobiological studies of psychopathology.

Let us first take a common environment → behavior example described by Lewis (1990), which begins with the observation that intrusive mothers of 3-month-old infants

are likely to have insecurely attached children at 1 year. The bidirectional component is that the mother's overstimulation is related to the child's behavior in children who are not socially oriented at 3 months of age, that is, those who prefer to play with and look at toys rather than people. These children often have mothers who are overstimulating, and the result is an insecurely attached child. In this example, the parent's behavior affects the child's behavior, but the parent's behavior was affected by the child's earlier behavior. Documenting these circular social-developmental patterns, as Lewis calls them, wherein child causes affect the environment and environmental causes affect the child, presents analytic difficulties:

Such models have intrinsic appeal, but by their nature are difficult to test. Nonlinearity requires a mathematics that still eludes us. Moreover, it is difficult not to treat a child or an environmental characteristic as a "pure" quantity even though we might know better. (Lewis, 1990, p. 25)

Now we turn briefly to some across-level bidirectional examples involving the levels of neural activity, behavior, and environment.

The hypothalamic-pituitary-adrenal (HPA) axis is the most widely studied stress system in animals and humans. Activation of the system in the face of threat, trauma, or other stresses can be determined in humans by measuring the increase (from basal levels) in the neurosecretory hormone cortisol found in saliva. Base levels of cortisol follow a circadian rhythm, being high shortly after awakening in the morning and declining throughout the day. A normative response to stress is a rise in cortisol level that shows up in saliva about 20 minutes after the stressful encounter, followed by a fairly rapid return to baseline. The rise in cortisol helps to focus and coordinate cognitive, emotional, behavioral, and metabolic activity in the face of a stressful psychosocial or physical environmental event, thus constituting a bidirectional relationship across three levels (environment, neural activity, behavior). Whereas brief elevations in cortisol in response to acute stress improves the developing child's ability to manage stressful experiences, chronic hyperactivity of the HPA axis may lead to neuronal loss in the hippocampus, inhibit neurogenesis, delay myelination, create abnormalities in the normative process of synaptic pruning, and thereby contribute to impairments in affective and cognitive functioning (review in Cicchetti & Rogosch, 2001b). On the other hand, in some children, exposure to chronic stress, such as persistent maltreatment, leads to hypocortisolism (reduced

adrenocortical secretion), which adversely affects neural development, the development of social and behavioral competence, as well as immunocompetence (cortisol activates the immune system; Cicchetti & Rogosch, 2001a; Granger, Weisz, McCracken, Ikeda, & Douglas, 1996; Gunnar & Davis, 2003; J. Hart, Gunnar, & Cicchetti, 1995). To our knowledge, the developmental psychobiology of the HPA stress reaction has not yet been taken to the genetic level in humans, but that has been accomplished in rodents (Meaney et al., 1996).

So, although Gunnar and Davis (2003) refer to the probabilistic-epigenetic framework as "overwhelmingly complex," they and their colleagues working on the HPA system have managed to implement it quite well across three of the four levels of analysis in human beings.

Ubiquity of Gene-Environment Interaction in Individual Development

The organism-environment interrelationship is at the heart of developmental psychology and psychopathology. Much of what passes for gene-environment interaction is actually organism-environment interaction. As an aside, it is telling that what represents the heart of developmental analysis is rarely found in the population form of behavioral genetics. For sheerly statistical constraints (Wahlsten, 1990), heritability analysis rarely finds gene-environment interaction.

It is ironic that until the advent of high-level statistical tools such as the analysis of variance and the concomitant statistical estimates of heritability, the omnipresence of gene-environment interactions, called the *norm of reaction* in biology, was taken for granted. In 1909, Woltreck introduced the notion of the norm of reaction to operationally and experimentally define Johannsen's (1909) newly coined concepts of gene, genotype, and phenotype. As pointed out by Dunn (1965), Johannsen's synthesis was magnificent and stimulated great progress in experimental genetics because of the analytic clarity of his concepts. However, Woltreck, while acknowledging the general utility of Johannsen's constructs, felt that Johannsen's concept of genotypic influences on phenotypic outcomes under different rearing circumstances was incorrect. Woltreck portrayed Johannsen's understanding of phenotypic development as what Gottesman (1963) introduced into psychology as a reaction range: the preservation of relative phenotypic differences between different genotypes across a number of rearing environments (the more or less parallel lines on the left side of Figure

17.2; Gottesman's depiction is shown in Figure 17.3). The insufficiency (i.e., the lack of generality) of the reaction range concept, in contrast to the norm of reaction, will be discussed later in this chapter.

When Woltereck (1909) experimentally examined the influence of three different quantities of nourishment on the development of head size (helmet height) in three geographic varieties of the freshwater crustacean daphnia

Figure 17.2 Woltereck's interpretation of Johannsen's notion of the genotype's influence on phenotypic expression (predicted) and the actual results (obtained) of rearing three geographic varieties of *Hyalodaphnia cucullata* (females) on different levels of nourishment. Adapted and translated from "Weitere Experimentelle Untersuchungen über Artveränderung, speziell über das Wesen Quantitativer Artunterschiede bei Daphniden" [Further experimental investigations of species modification, particularly the nature of quantitative species differences in daphnia], by R. Woltereck, 1909, *Verhandlungen der Deutschen Zoologischen Gesellschaft*, 19, pp. 138–139, figs. 11 and 12.

(*Hyalodaphnia cucullata*), he obtained three very different curves in moving from the deprived through the normal to the enriched conditions of nutrition, as shown on the right side of Figure 17.2. Woltereck regarded the outcomes of these kinds of developmental experiments—ones designed to empirically determine the phenotypic curves for a range of rearing conditions in closely related but genetically distinct groups—as defining what Johannsen (1909) called the genotype. The generality of Woltereck's concept of the unpredictability of the phenotype of similar genotypes when confronted with novel rearing circumstances has been validated repeatedly in psychology (Erlenmeyer-Kimling, 1972), as well as in biology, down to the present day, and these results conform to the notion that epigenetic outcomes are probabilistic rather than pre-determined (Gottlieb, 1970, 1991).

For example, in one of the most ambitious studies of reaction norms, Gupta and Lewontin (1982) examined the number of bristles, viability, and development time in 32 strains from three different natural populations of fruit flies (*Drosophila pseudoobscura*) at two egg densities and three temperatures. They found a considerable number of reversals in relative position in pairwise comparisons between genotypes (e.g., 30% to 45% reversals when temperature was changed). They conclude, "Thus, it is not possible to characterize one genotype as having a higher bristle number or faster development than another, since this can only be relative to a given environment" (p. 947). Their results contradict rather strongly the reaction-range concept, as well as the utility of the breakdown of phenotypic variance into independent hereditary and environmental components as gleaned from heritability estimates.

As our experiments show, norms of reaction are not parallel, so effects of changing environment and genotype on variance are general. . . . A second consequence of the complex norms of reaction displayed by genotypes in natural populations is that the ordering of different populations in terms of the amounts of the genetic variation they contain may change with environment. . . . A third, and probably most important, consequence of the observed reaction norms is the "myopia" of selection. This is most clearly seen in the viability results . . . genotypes favored by natural selection at 14° C may be quite poor at other temperatures. In fact, there is almost a complete reversal of viabilities in Strawberry Canyon heterozygotes between 14°C and 21°C. (p. 945)

Thus, the limitations implied by the norm of reaction are best viewed as developmental, rather than strictly or solely genetic. The absence of strict predictability is now recognized in many quarters as a defining feature of develop-

Image rights not available

Figure 17.3 (A) Phenotypes are typically sensitive to changes in the environment. Here, the phenotypic value of each of three genotypes is plotted in two different environments (1 and 2). The environments can be the two sexes, social and physical environments (for example, diet, temperature), or alternative genotypes at a second genetic locus that affect the trait. The line joining the phenotypes of the same genotype in different environments is the norm of reaction of the genotype. Here, there are differences in the mean value of the quantitative trait between the two environments, but alternative genotypes react in the same manner to the change in mean. The rank order and absolute magnitude of the difference between the genotypes remains constant, and the norms of reaction are parallel. In this case, there is no statistical genotype-by-environment (GEI) interaction. (B) Genotype-by-environment interactions occur when there is a change of rank order in the two environments. (C) Interactions also occur when there is a change of variance with sex, environment, or genetic background. Adapted from “Quantitative Trait loci in *Drosophila*,” by T. F. C. Mackay, 2001, *Nature Reviews-Genetics*, 2, pp. 11–20. Reproduced with permission of the author and *Nature Reviews-Genetics*, copyright 2001 Macmillan Magazines Ltd.

ment. It is specifically taken into account in such diverse formulations as holistic views of personality (Magnusson & Törestad, 1993), dynamic systems theory (Thelen, 1990), individual-socioecological approaches (Valsiner, 2001, pp. 49ff), and developmental contextualism (Lerner, 2002).

As documented by Wahlsten (1990), the calculation of heritability using the analysis of variance (ANOVA) is often insensitive to the statistical interaction of gene and environment because the detection of such interactions by that statistical procedure requires larger *N*s than are usually available in studies using humans.¹ The other weakness (not to say distortion) of relying on ANOVA-like statistics to determine the presence of a gene-environment

interaction is the peculiar conclusion (for the statistically uninitiated) that obvious empirical interactions do not qualify as statistical interactions, such as the example in the left side of Figure 17.2. To clarify this point further, Figure 17.4 portrays three different forms of norms of reaction for phenotypes that vary quantitatively, such as height, weight, IQ, and amount of extraversion.

This hypothetical figure portrays the phenotypic outcomes of three genotypes studied over two environments. In the left panel, there is said to be no gene-environment interaction because the genotypes have maintained their ranking and the magnitude of the differences among them, resulting in parallel reaction norms. Obviously, this is a very specialized (sheerly statistical) use of the term interaction because the phenotype associated with each of the genotypes has changed from environment 1 to environment 2. The middle and right panels are said to be examples of gene-environment interaction because in the middle panel the reaction norms cross, and in the right panel a phenotypic difference among them is brought out only in environment 2. The term environment is used here in its broadest connotation: “The environments can be the two sexes, physical environments . . . or alternative genotypes

¹ As the next paragraph makes clear, the statistical concept of an interaction does not have the same meaning as the omnipresent notion of an interaction denoting a primary inseparability or interconnectedness of genes and environment, in the sense that all outcomes are the result of genes operating in a particular developmental milieu and that outcomes are likely to change when the developmental milieu changes. The statistical concept of interaction recognizes only certain changes as qualifying for the term interaction, as described in the next paragraph.

Figure 17.4 Gottesman's schematic illustration of the reaction range concept for four hypothesized genotypes. RR = Reaction range in phenotypic IQ. *Source:* From "Genetic Aspects of Intelligent Behavior" (p. 255), by I. I. Gottesman, in N. R. Ellis (Ed.), *Handbook of mental deficiency: Psychological theory and research*, 1963, New York: McGraw-Hill.

at a second [locus] that affect the trait" (Mackay, 2001, p. 12). Earlier we asserted that gene-environment interaction is the rule; in light of the above, we now adopt the term gene-environment *coaction* to implicate the interconnectedness, if not the statistical interaction, of gene-environment interrelations as far as individual development is concerned.²

Norm of Reaction versus Reaction Range

The norm of reaction holds that, if we know the phenotypic outcome of two genotypes under one rearing (environmental) condition, we cannot predict their relative standing when these genotypes (actually, organisms) are reared in a different environment. Gottesman's (1963) reaction range concept, on the other hand, presumes that the genotype imposes a priori limits (a range) on the expression of a

phenotype (Platt & Sanislow, 1988), such that the phenotype has upper and lower bounds that cannot be transcended. In Waddington's (1957, p. 36) terms, the developing phenotype is genetically buffered or genetically canalized (see Figure 17.5). This state of affairs is diagrammed in Figure 17.3. On the right side of the figure, the reaction ranges of the four genotypes are bracketed, as depicted by Gottesman.

It happens that there is an empirical study in the psychological literature that explicitly addresses the reaction norm concept, a study by R. M. Cooper and Zubek (1958). The results very clearly support the reaction norm concept. It is interesting to note that the study was carried out with the idea of a reaction range in mind and that it is cited by Gottesman (1963, p. 273) as supporting the reaction range concept. Cooper and Zubek reared maze-bright and maze-dull rats in either an enriched or a restricted environment and then tested them in a Hebb-Williams maze. Because they had the reaction range concept in mind in performing the experiments, they thought that the learning of both the bright and dull rats would improve relative to each other under the enriched rearing circumstances and would be poorer relative to each other when reared under the restricted (deprived) condition. (This prediction is illustrated on the left side of Figure 17.5.) Instead, as shown on the right side of Figure 17.5, they found equality of performance under both rearing conditions. The dull rats made as few errors as the bright rats after enriched rearing, and the bright rats made as many errors as the dull rats after restricted rearing.

When the so-called bright and dull rats were tested in the Hebb-Williams maze after being reared in their usual way (neither enriched nor deprived), a significant difference between the strains appeared (middle points, right side of Figure 17.5). The reason is that this developmental situation repeats the rearing condition under which the original selective breeding for superior and inferior performance was carried out (Hughes & Zubek, 1956). If the reaction range idea were correct and the genes coded for a range of learning ability (brackets on the right side of Gottesman's Figure 17.3), when these rat strains were reared under enriched or restricted conditions, the relative difference between them would be preserved. Instead, the experiment shows that the genes are part of a developmental system or manifold. The highly specific consequences of rearing under a certain developmental condition were realized by selective breeding under that condition: The animals were selectively bred on the basis of their developmental reaction to that rearing condition. And, as called for by the norm of reaction concept, selective breeding under one developmental regimen does

²In agreement with our premise, at the conclusion of his critique of the ANOVA and its use in behavioral genetics, Vreek (2000, p. 44) writes, "Behavior geneticists . . . should acknowledge that an analysis of variance is a statistical method that does not fit reality and should be judged against the background of the best material model we have of development, which is one of dynamics and interactions." If the ANOVA is inadequate for getting at the development aspect of behavioral genetics, then it follows that it must not be an appropriate statistical tool for developmental psychology, where it is very widely used. It is clear that we desperately need a more developmentally adequate statistical method to replace the ANOVA.

Figure 17.5 Behavioral reaction range (predicted) and norm of reaction (obtained) for maze-bright and maze-dull rats' performance in a Hebb-Williams maze after rearing in three different environments. Obtained deprived and enriched data points are from Cooper and Zubek (1958); obtained usual data points are from Hughes and Zubek (1956). Only the obtained usual data points are significantly different from each other.

not predict outcomes under different rearing conditions. The results of selection depend on the entire developmental manifold, not only on the genes that are involved: To get stable outcomes, the developmental conditions have to remain the same from generation to generation (Gottlieb, 2002a).

A recent study by Kathryn Hood (2005) provides striking support for the developmental manifold idea in the continued dependence of the phenotypic outcome on the specifics of the rearing environment utilized as the basis for selective breeding. Hood and her colleague, Robert B. Cairns, were interested in selectively breeding mice for the expression of high and low levels of aggression. To this end, they placed animals in social isolation after weaning (such rearing enhances aggressive tendencies in some mice) and observed them in aggressive encounters around 4 weeks later. After only several generations of selective breeding based on the animals' response to isolation rearing in each generation, the high and low lines were clearly differentiated. Hood was interested in the question of gene-environment coaction, so after five generations of selective breeding, she raised half of each line in social conditions after weaning and examined their attack frequency in comparison to the other half of the lines reared in social isolation.

As can be seen in Figure 17.6, high-line mice reared under social conditions ("group") were as nonaggressive as the low-line mice, whereas the high-line mice reared in isolation continued to show a high level of aggressive attack behavior. A nice demonstration of gene-environment coaction: the continued dependence of the selectively bred attack response on the rearing environment in which it was selectively bred. What may come as a surprise to some readers is that, after a further 34 generations of selection, the aggressive behavior of the high-line mice is no less dependent on isolation rearing for its manifestation. As shown in Figure 17.7, the attack frequency of the high-line mice drops to slightly below that of the low-line mice when the mice are socially reared in the 39th generation. In Figure 17.7, the 500 line is an unselected line, and their attack frequency is midway between the high and low lines when they are reared in isolation and drops to zero when they are reared socially—yet another example of gene-environment coaction, if we assume a genetic difference between the selected and unselected lines.

Behavioral development is not unique in its continued dependence on gene-environment coaction. Even under strong evolutionary selection pressure, morphological variation is similarly dependent (Griffiths, Owen, & Burke,

Figure 17.6 After five generations of selective breeding for high and low aggression as a consequence of isolation rearing, Hood (in press) reared the two lines under social conditions (“group”) and found no differences in aggressive behavior (i.e., the high line dropping to the level of the low line when socially reared). Modified from K. Hood, 2005.

1999). Both the behavioral and morphological findings support the idea that understanding development requires a *relational* concept of causality: Development outcomes are a consequence of at least two specific components of coaction from the same or different levels of analysis (Gottlieb & Halpern, 2002). The basic notion here is that the emergent products of development are epigenetic, not just genetic, and this continues to be the case even when we are considering the evolutionary process. A small number of evolutionary biologists are now actively espousing the continued epigenetic basis of morphological evolutionary outcomes, in the sense that the genes correlated to these morphological outcomes may change during the process of evolution while the outcomes are kept stable by epigenetic mechanisms (reviewed in Gottlieb, 2002a, pp. 54–55).

This completes our review of the major contentions of the probabilistic-epigenetic framework. It now remains to give a detailed application of the framework to the development of a specific form of psychopathology: Attention-Deficit/Hyperactivity Disorder. We have chosen to focus on ADHD because we are most conversant with that literature and can thus give a more instructive treatment than would be possi-

Figure 17.7 After 39 generations of selective breeding for high and low aggression as a consequence of isolation rearing, Hood (in press) reared the two lines under social conditions (“group”) and found no differences in aggressive behavior (i.e., the high line dropping to slightly below the level of the low line when socially reared). The control line is an unselected line. Modified from K. Hood, 2005. Further discussion in text.

ble if we tried to embrace several disorders, or the field in general. Elsewhere, we have dealt with other disorders in an illustrative fashion (Gottlieb & Halpern, 2002).

EXTENDED EXAMPLE

Although often considered a benign right of passage in adolescence, cigarette smoking is the leading cause of preventable death in the United States, responsible for nearly 1 in 5 deaths annually (Brodish, 1998). Cigarette smoking is associated with a variety of diseases, including coronary heart disease and lung cancer. Moreover, experimentation with cigarettes frequently precedes use of illegal substances (Kandel & Yamaguchi, 1993). In addition to disastrous health effects, cigarette smoking represents an enormous financial burden to the country’s health care system (Williams & Ziedonis, 2004). In sum, cigarette smoking represents a major public health problem. For the remainder of the chapter, we consider elevated rates of cigarette smoking among youth diagnosed with ADHD. We rely on a probabilistic-epigenetic perspective to better

understand why this association exists, as well as to clarify directions for future research.

Over 3 decades ago, Borland and Heckman (1976) reported that childhood hyperactivity was associated with increased risk for cigarette smoking in adulthood. Specifically, in a 25-year follow-up study of individuals who had been designated as hyperactive in childhood, 80% smoked cigarettes as adults. This compared to a 25% rate of smoking among their biological brothers. At the time, the finding was unanticipated and interpreted broadly as a negative outcome associated with childhood hyperactivity.

However, in the past decade, four different research groups have documented that childhood ADHD is associated with an increased risk of smoking in adolescence and early adulthood using both community (Lambert & Hartsough, 1998) and clinic (Barkley, Fischer, Edelbrock, & Smallish, 1990; Milberger, Biederman, Faraone, & Chen, 1997; Molina & Pelham, 2003) samples. Although these studies differed in the definitions of smoking and the age at which participants were assessed, they share a common finding that ADHD is associated with a twofold increase risk for smoking. For example, Lambert and Hartsough reported 46% of ADHD versus 24% of comparison youth smoked on a daily basis at age 18. Barkley et al. reported smoking rates of 48% and 27% for ADHD and comparison youth, respectively, in the adolescent follow-up of their clinic-based sample. Molina and Pelham reported 30% of adolescents with a childhood history of ADHD were daily smokers compared to 12% of the community comparison group. Finally, Milberger et al. reported smoking rates of 19% and 10% for ADHD and comparison youth, respectively, in the follow-up of their clinic-based sample. The lower rate of smoking reported by Milberger and colleagues was likely due to the younger age of the sample at follow-up. Finally, at least one clinic-based study suggested that the twofold increase of smoking associated with ADHD persists into middle adulthood and may even worsen, given that ADHD adults appear to be less successful in quitting smoking than non-ADHD adults (O. F. Pomerleau, Downey, Stelson, & Pomerleau, 1995).

Although it has long been known that childhood ADHD is predictive of adolescent substance (ab)use, many studies have demonstrated that this relationship is an artifact of the overlap between both ADHD and substance (ab)use with conduct problems (Disney, Elkins, McGue, & Iacono, 1999; Fergusson, Lynskey, & Horwood, 1993; Lynskey & Fergusson, 1995; Mannuzza, Klein, Bonagura, et al., 1991). A number of recent studies have questioned this long-standing position, arguing instead that it is the combination (i.e., the interaction) of ADHD and Conduct Disor-

der that is associated with increased risk for substance use and abuse (Chilcoat & Breslau, 1999; Flory, Milich, Lynam, Leukefeld, & Clayton, 2003; Klein, 2002; Molina, Smith, & Pelham, 1999). Despite these conflicting findings, there is good evidence that ADHD is *uniquely* related to cigarette smoking, even after controlling comorbid conditions, including Conduct Disorder, as well as demographic factors (e.g., ethnicity, familial smoking) that are known risk factors for smoking (Burke, Loeber, & Lahey, 2001; Milberger, Biederman, Faraone, & Chen, 1997; Milberger, Biederman, Faraone, Chen, & Jones, 1997; Molina & Pelham, 2003; Rhode, Kahler, Lewinsohn, & Brown, 2004; Riggs, Mikulich, Whitmore, & Crowley, 1999). Moreover, ADHD is the only psychiatric disorder that consistently precedes the onset of daily smoking (Rhode et al., 2004). Collectively, these studies indicate that the increased rate of smoking observed among ADHD youth is a real phenomenon that merits empirical investigation. For the remainder of this chapter, we rely on a probabilistic-epigenetic perspective to organize the results of previous studies and inform future research.

Multiple Levels of Influence

Figure 17.1 provided a fully sketched model of probabilistic epigenetic. The four general classes of influence that are depicted in Figure 17.1 are intended to serve a heuristic purpose; there are obviously subclasses of influences within each (e.g., environmental influences can range from cultural factors to family processes; neural influences can range from neurotransmitters to brain structure). Figure 17.1 is intended to convey three points. First, there are multiple levels of influence on individual development. Second, it is the coactions within (horizontal) and between (vertical) levels that drive development. Coactions imply bidirectionality between levels and are typically represented by experience. Third, vertical and horizontal coactions occur across time (i.e., development is directional). Next, we consider the environmental, behavioral, neural, and genetic influences that may help to explain elevated rates of cigarette smoking among ADHD youth.

Environmental Influences

There are a variety of environmental factors that have been implicated in the onset and maintenance of cigarette smoking. At a broad level, these include school-level contextual factors that serve to promote or discourage individual smoking behavior (Novak & Clayton, 2001). More immediate factors include the presence of familial and peer smoking (Tercyak, Lerman, & Audrain, 2002). Individuals who

have parents and especially peers who smoke are at increased risk of an early onset and stable smoking over time (Chassin, Presson, Pitts, & Sherman, 2000; Fergusson, Lynskey, & Horwood, 1995). In addition, family contextual factors, including lower socioeconomic status (SES) and less supportive family environments, are also risk factors for smoking (Chassin et al., 2000; Fergusson et al., 1995).

Many of these environmental risk factors may be especially salient for ADHD youth. For example, childhood ADHD is predicted by maternal smoking during pregnancy (Milberger, Biederman, Faraone, Chen, & Jones, 1996; Milberger, Biederman, Faraone, Guite, et al., 1997). Moreover, the increased risk of smoking associated with having a sibling who smokes appears to be stronger if that sibling has ADHD (Milberger, Biederman, Faraone, Chen, & Jones, 1997). In addition, the increased risk of smoking that is associated with having peers who smoke (Chassin et al., 2000; Milberger, Biederman, Faraone, Chen, & Jones, 1997; Tercyak, Peshkin, Walker, & Stein, 2002) may be exacerbated among ADHD youth, given that they report spending more time with their peers (versus family) than do non-ADHD youth (Whalen, Jamner, Henker, Delfino, & Lozano, 2002). Finally, the increased risk of adolescent smoking related to low SES (Fergusson et al., 1995; Gilbert & Gilbert, 1995) is noteworthy given that low SES is also predictive of ADHD (Biederman et al., 1995; Scahill & Schwab Stone, 2000).

In sum, a variety of environmental factors are associated with the emergence of smoking. Whereas some of these factors are common to both ADHD and non-ADHD youth (e.g., low SES, school-level influences), others may be particularly salient for ADHD youth (e.g., familial smoking). Any comprehensive explanation of increased rates of smoking among ADHD youth should acknowledge these environmental factors.

Behavioral Influences

The *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* distinguishes ADHD youth in terms of their predominant pattern of inattentive and hyperactive-impulsive behaviors. Specifically, youth are differentiated into inattentive, hyperactive-impulsive, and combined subtypes (American Psychiatric Association, 1994; Lahey et al., 1994). Five studies have demonstrated the importance of differentiating dimensions of ADHD as they relate to cigarette smoking. First, using a large community-based sample, Tercyak and colleagues (Tercyak, Lerman, et al., 2002) reported that individuals exhibiting elevated levels of inattentive symptomatology were three times more likely to have ever smoked and to be current smokers relative to in-

dividuals who did not exhibit elevated levels of inattentive symptomatology. In contrast, elevated levels of hyperactive-impulsive symptomatology were not associated with increased risk of smoking. Second, in the context of a smoking cessation program for normal adults, Lerman and colleagues (2001) reported that smoking for stimulation and smoking for withdrawal relief were both uniquely associated with inattentive but not hyperactive-impulsive behaviors, even after accounting for concurrent depressive symptomatology. Third, two well-characterized clinic samples of youth with disruptive behavior disorders demonstrated that inattentive, but not hyperactive-impulsive, behaviors were a significant predictor of adolescent tobacco use even after controlling for Conduct Disorder (Burke et al., 2001; Molina & Pelham, 2003). Fourth, a composite measure of neuropsychological tests that represented attention/executive functioning was predictive of substance use and dependence symptoms over an 8-year period, even after controlling for Conduct Disorder, learning disabilities, demographic factors, and family history of substance use (Tapert, Baratta, Abrantes, & Brown, 2002).

Whereas inattentive behaviors may be directly related to cigarette smoking, hyperactive-impulsive behaviors may play an indirect role in increasing the risk of cigarette smoking among ADHD youth. Hyperactive-impulsive behaviors are conceptually similar to the personality dimension of novelty seeking. Individuals characterized by high levels of novelty seeking are described as exploratory, curious, and impulsive. There is indication that novelty seeking is elevated in both adults who smoke (Gilbert & Gilbert, 1995; Heath, Madden, Slutske, & Martin, 1995) and adults with ADHD (Downey, Pomerleau, & Pomerleau, 1996). Moreover, among both adolescents and adults with ADHD, those who smoke report higher levels of novelty seeking than those who do not smoke (Conners et al., 1996; Downey et al., 1996; O. F. Pomerleau et al., 1995; Tercyak & Audrain-McGovern, 2003). These findings suggest that ADHD youth who exhibit elevated levels of hyperactive-impulsive behaviors may be more likely to experiment with smoking and may do so at earlier ages than non-ADHD youth (Heath et al., 1995).

ADHD subtypes may also be differentially related to smoking due to their overlap with other psychiatric disorders. In general, ADHD youth are known to exhibit high rates of comorbidity with other psychiatric disorders (Angold, Costello, & Erkanli, 1999; Biederman, Newcorn, & Sprich, 1991; Jensen, Martin, & Cantwell, 1997). Whereas inattentive-type youth appear to be at increased risk for exhibiting internalizing disorders, combined-type youth appear to be at increased risk for exhibiting externalizing

disorders (Eiraldi, Power, & Nezu, 1997; Nolan, Volpe, Gadow, & Sprafkin, 1999; Willcutt, Pennington, Chhabildas, Friedman, & Alexander, 1999). Both internalizing and externalizing disorders are associated with increased rates of cigarette smoking (Upadhyaya, Deas, Brady, & Kruesi, 2002). Indeed, when multiple psychiatric disorders are considered simultaneously, depression and Conduct Disorder are among the most robust predictors of cigarette smoking (Brown, Lewinsohn, Seeley, & Wagner, 1996; Costello, Erkanli, Federman, & Angold, 1999; Dierker, Avenevoli, Merikangas, Flaherty, & Stolar, 2001; Lerman et al., 2001; Riggs et al., 1999). Thus, although elevated levels of inattentive and hyperactive-impulsive symptoms may serve as risk factors for cigarette smoking, internalizing and externalizing disorders that frequently co-occur with ADHD may represent additional risks for cigarette smoking.

In sum, a variety of personality and behavioral factors are associated with the emergence of smoking. Many of the risk factors for adolescent/adult smoking (e.g., depression, Conduct Disorder, novelty seeking) are also overrepresented among ADHD youth. Any comprehensive explanation of increased rates of smoking among ADHD youth should acknowledge these behavioral factors.

Neural Influences

As noted earlier, the four levels of influence depicted in Figure 17.1 are intended to serve a heuristic function. There are a variety of sublevels of influence within any particular level. For purposes of our example, we focus on neurotransmitters as the primary neural influence related to the association between ADHD and smoking.

It has long been known that altered neurotransmitter systems are implicated in ADHD (Kornetsky, 1970; Wender, 1975). Historically, this association stemmed from the observation that medications that were effective in treating ADHD exerted their effect by influencing areas of the brain rich in catecholamines (i.e., dopamine [DA], norepinephrine [NE]). Over time, it has become clear that DA and NE systems play complementary roles in modulating higher-order processes involving attention and arousal that are relevant to both general neurological functioning (Tucker & Williamson, 1984) and ADHD in particular (Malone, Kershner, & Swanson, 1994; Mercurigliano, 1999; Pliszka, McCracken, & Maas, 1996; Solanto, 1998). For example, Malone and colleagues suggested that ADHD is associated with increased levels of NE and decreased levels of DA, and that treatment with psychostimulants (e.g., Ritalin) may ameliorate behavioral and cognitive deficits by reversing these neurotransmitter imbalances.

Cigarette smoking exerts a variety of psychological and physiological effects via the role of nicotine that are directly relevant to ADHD (Rezvani & Levin, 2001). In a series of double-blind placebo controlled studies, Levin and colleagues demonstrated that the administration of nicotine resulted in improved performance on indices of attention that are impaired in ADHD youth/adults. For example, 56% of ADHD adults were rated as exhibiting “much improved” or “very much improved” ADHD symptoms when receiving a nicotine patch by clinicians who were blind to their medication status; this compared to 0% rates of improvement among adults in a placebo condition (Conners et al., 1996; Levin et al., 1996). Nicotine was also associated with faster and less variable reaction times on a continuous performance task among ADHD adults (Conners et al., 1996; Levin, Conners, Silva, Canu, & March, 2001; Levin et al., 1996). A similar pattern of improvements in objective indices of attention associated with nicotine has also been demonstrated among nonsmoking, non-ADHD adults (Ernst, Heishman, Spurgeon, & London, 2001; Levin et al., 1998). These latter studies have helped rule out the possibility that previous reports regarding the beneficial effects of nicotine were due to the relief of nicotine withdrawal among smokers.

The most consistently offered explanation for the beneficial effects of nicotine on ADHD symptoms and associated impairments involves catecholamine changes. Although the specific mechanisms are not clear, it appears that nicotine results in the release of DA and NE, as well as a variety of other neurotransmitters, including acetylcholine (Levin et al., 1998; Rezvani & Levin, 2001). Consistent with this explanation, a recent neuroimaging study demonstrated that nicotine acts in a manner similar to psychostimulants with respect to striatal dopamine transporter binding (Krause et al., 2002).

In addition, as noted earlier, three studies have reported higher levels of novelty seeking among ADHD adults who smoke relative to ADHD adults who do not smoke (Conners et al., 1996; Downey et al., 1996; O. F. Pomerleau et al., 1995). All three of these studies measured novelty seeking using Cloninger's Tridimensional Personality Questionnaire (TPQ) scale. Interestingly, the TPQ was developed to fit into a larger biologically based model of personality (Cloninger, Svrakic, & Przybeck, 1993). The novelty-seeking scale of the TPQ was intended to index the “activation” system that involves the dopaminergic system (Downey et al., 1996). To the extent that the novelty-seeking scale of the TPQ indexes individual differences in dopaminergic functioning, elevated levels of novelty seeking among ADHD adults who smoke provide additional, al-

beit indirect, support for involvement of the dopaminergic system regarding elevated rates of smoking among ADHD youth/adults.

In sum, the primary neurotransmitter systems that have been implicated in the emergence and maintenance of ADHD are affected by cigarette smoking. For example, whereas ADHD is associated, in part, with low levels of synaptic dopamine, cigarette smoking influences a variety of neurotransmitter systems, including increasing levels of dopamine. Any comprehensive explanation of increased rates of smoking among ADHD youth should acknowledge the role of neurotransmitters.

Genetic Influences

It is well established that ADHD runs in families. For example, biological parents and siblings of children with ADHD are 2 to 7 times more likely to have met diagnostic criteria for ADHD than are parents and siblings of control children (Faraone & Biederman, 1999). The observation that ADHD runs in families provided the impetus for research on genetic influences associated with the disorder. Early efforts included quantitative behavioral genetic studies using twin samples and, to a lesser extent, family and adoption studies (Kuntsi & Stevenson, 2000). More recently, molecular genetic studies of ADHD have been initiated.

The combined success of pharmacological agents that influence the catecholamines in the treatment of ADHD and the existence of models implicating the catecholamines in the etiology of ADHD resulted in dopamine genes being the initial target of molecular genetic studies of ADHD (Swanson et al., 2000). Although in their infancy, molecular genetic studies have indicated that both dopamine transporter (DAT) and dopamine receptor (DRD4) genes are associated with ADHD. Although not universally true, the association between the 10 copy repeat allele of the DAT gene and ADHD has been replicated in multiple studies (Cook, 1999). In addition, there are consistent indications that the 7 repeat allele of the DRD4 gene is associated with ADHD (Faraone, Doyle, Mick, & Biederman, 2001). In both cases, ADHD is associated with specific polymorphisms involving decreased levels of dopamine, due either to enhanced reuptake efficiency (DAT) or suboptimal receptor cells (DRD4).

Tercyak and colleagues (Tercyak, Peshkin, et al., 2002) reviewed the genetic similarities between ADHD and cigarette smoking. For example, like ADHD, cigarette smoking has been described as being intergenerational (i.e., runs in families) and highly heritable. Moreover, the reinforcing properties of cigarette smoking, like other addictive drugs, are attributed to the effect of nicotine on dopamine trans-

mission, as dopamine is involved in reward centers of the brain. Given this association, dopamine genes have also been the early targets of molecular genetic studies of cigarette smoking.

Similar to ADHD, DAT and dopamine receptor (DRD2) genes have been the focus of molecular genetic studies of cigarette smoking (Lerman et al., 1998, 1999; Sabol et al., 1999). Preliminary results have indicated that the 9 repeat allele of the DAT gene predicted less smoking, a later onset of smoking, and longer quit (cessation) periods among active smokers (Lerman et al., 1999). Lerman and colleagues also reported a gene-by-gene interaction. Specifically, the decreased risk of smoking associated with the 9 repeat allele of the DAT gene in their sample was enhanced for individuals with the A2 allele of the DRD2 gene. Lerman and colleagues interpreted this finding as suggesting that “the availability of synaptic dopamine may decrease the need for nicotine only if there are sufficient receptors for normal dopamine transmission” (p. 18).

Sabol and colleagues (1999) attempted to replicate the Lerman et al. (1999) findings. Like Lerman and colleagues, they, too, reported that the 9 repeat allele of the DAT gene was associated with less smoking. However, in their study, this was due to greater rates of smoking cessation among individuals with the 9 repeat allele, not reduced rates of smoking initiation. Although there was some indication of an interaction between DAT and DRD2 genes, in contrast to Lerman et al.’s findings, this interaction was not statistically significant.

Sabol and colleagues (1999) also noted that individuals with the 9 repeat allele of the DAT gene reported significantly lower levels of novelty seeking (which was once again measured using Cloninger’s TPQ scale) than individuals without the 9 repeat allele. Moreover, current smokers reported significantly higher levels of novelty seeking than did former smokers. These results suggested that the personality dimension of novelty seeking mediated the association between polymorphisms in the DAT gene and elevated rates of smoking. This interpretation is consistent with the idea of gene effects being contingent on life experiences.

In sum, there is an emerging literature on the molecular genetics of both ADHD and cigarette smoking. Although not conclusive, there are early indications that polymorphisms of the dopamine transporter gene that are associated with *decreased* levels of synaptic dopamine are related to *increased* levels of novelty seeking, *increased* risk for ADHD, and *increased* rates of smoking. That said, these relationships are clearly complex and involve moderation both by other dopamine genes (Kirley et al., 2002) and other neurotransmitters (e.g., acetylcholine; Kent et al.,

2001; Todd, Lobos, Sun, & Neuman, 2003) and as yet unidentified life experience (environmental) factors, the necessary participation of which was described in the introductory section of this chapter. Any comprehensive explanation of increased rates of smoking among ADHD youth should acknowledge (atypical) genetic factors.

Self-Influences

Although not explicitly represented in Figure 17.1, the probabilistic-epigenetic perspective emphasizes that individuals contribute to their own development in the sense that they actively seek to structure their experience in ways that are maximally beneficial to them. This idea that individuals actively contribute to their own development is a common feature of systems theories espousing an organismic perspective (Lerner, 2002; Magnusson & Cairns, 1996; Overton & Reese, 1973). In the smoking literature, it is widely acknowledged that there are a variety of reasons people smoke, including management of negative affect, improvement of concentration, and to change arousal states (increase energy or relax). Although many of these common explanations are in need of further empirical scrutiny (Kassel, Stroud, & Paronis, 2003), they are consistent with the idea that individuals use smoking as a means to achieve certain desired states. Building on these beneficial aspects of smoking, one explanation for increased rates of smoking among ADHD youth involves a self-medication hypothesis (Khantzian, 1997; Klein, 2002; Wilens, 2002). The self-medication hypothesis implies that elevated rates of smoking among ADHD youth may be due in part to the ability of cigarette smoking to “treat” ADHD (and related) symptomatology and impairments.

Thus, to the extent that smoking ameliorates difficulties encountered by ADHD youth during the transition to adolescence, it may serve as a form of self-medication. Any comprehensive explanation of increased rates of smoking among ADHD youth should acknowledge efforts on the part of the individual to actively structure his or her experiences in a way that is maximally beneficial (e.g., enhanced mood; improved capacity for academic, occupational, or interpersonal success).

Linking Levels of Influence

A key feature of the probabilistic-epigenetic perspective is that no single level of influence operates independently. Rather, there are bidirectional relationships (i.e., coactions) between and within different levels of influence that, when considered collectively, are responsible for de-

velopment. In the sections that follow, we consider coactions that may be implicated in the increased rate of smoking among ADHD youth. We follow this by considering testable predictions that result from these coactions.

Environmental and Behavioral Coactions

Although ADHD youth are twice as likely to smoke as non-ADHD youth, a full half of ADHD youth do not smoke. Thus, despite the increased risk, interindividual differences in smoking behavior are an area of interest. At the behavioral level, it is well-known that inattentive, hyperactive-impulsive, and aggressive behaviors commonly exhibited by ADHD youth interfere with the development of peer relationships, resulting in their rejection by the larger peer group and risk for involvement in delinquent peer groups (Bierman & Wargo, 1995; Hinshaw & Melnick, 1995; Pelham & Bender, 1982; Pope, Bierman, & Mumma, 1991). In turn, their involvement in delinquent peer groups increases the likelihood that they will participate in behaviors and activities that violate societal norms, including early experimentation with illegal substances and cigarette smoking (Fergusson & Horwood, 1996; Fergusson, Woodward, & Horwood, 1999). Indeed, Marshal and colleagues (Marshal, Molina, & Pelham, 2003) recently reported that the association between childhood ADHD symptomatology and the quantity of cigarettes smoked in early adolescence was partially mediated by deviant peer affiliation. Thus, one route by which ADHD youth may come to experiment with cigarette smoking is through vertical coactions between environmental (i.e., delinquent peer group affiliation) and behavioral (i.e., ADHD, conduct problems) influences.

There are clearly other routes by which ADHD youth come to smoke that do not involve affiliation with delinquent peer groups and/or co-occurring conduct problems. As noted earlier, having parents who smoke increases the risk that children will smoke, due probably to a combination of access to cigarettes, modeling, and social reinforcement (Tercyak, Lerman, et al., 2002). Moreover, given that a majority of U.S. high school students report having experimented with cigarettes by age 17 (Tercyak, Peshkin, et al., 2002), most ADHD youth would be exposed to cigarette smoking regardless of the quality or nature of their peer relationships or family involvement in smoking.

Given that there are likely multiple ways in which ADHD youth may be exposed to smoking, future investigation may benefit from considering not only the smoking status of ADHD youth but also the age of onset of their smoking. For example, an *early onset* of smoking may result from affiliation with delinquent peers and be typical

for the subset of ADHD youth who score high on dimensions of novelty seeking and/or who have co-occurring conduct problems (i.e., ADHD combined-subtype youth). In contrast, a *later onset* of smoking may represent age-typical exposure via peers and/or family members and be typical of the subset of ADHD youth who do not affiliate with delinquent peers and who do not have co-occurring conduct problems (i.e., ADHD inattentive-subtype youth).

Consistent with this speculation, there is evidence that a history of early-onset conduct problems (i.e., prior to age 15) is associated with an early onset of smoking (i.e., prior to age 14), as well as increased risk for eventual nicotine dependence (Breslau, 1995). Stronger support for this speculation comes from a recent study that indicated that, whereas hyperactive-impulsive and oppositional defiant/conduct symptomatology were associated with an earlier age of cigarette experimentation, inattentive (but not hyperactive-impulsive or oppositional/conduct) symptomatology was associated with the quantity of cigarettes smoked in the past 6 months (Molina & Pelham, 2003).

Behavioral and Neural Coactions

Cigarette smoking increases nicotine in the body and influences a variety of neurotransmitters, including the catecholamines. In turn, changes in these neurotransmitter systems influence mood states and cognitive functioning (Levin et al., 1998). One consequence of the bidirectional relationship between smoking and changes in neurotransmitter systems is that smoking becomes associated with pleasurable mood, improved attention, and greater cognitive control (Coger, Moe, & Serafetinides, 1996; Gilbert & Gilbert, 1995). To the extent that these changes are perceived as beneficial, smoking behavior is reinforced.

Given that both the core behavioral and cognitive deficits (e.g., attention problems), as well as related affective difficulties (e.g., low self-esteem, anxiety, depression) of ADHD are affected by smoking, ADHD youth may perceive greater benefits from smoking compared to non-ADHD youth. Moreover, once they have started smoking, it may be more difficult for ADHD youth to quit smoking given that the psychobiological mechanisms associated with nicotine have ameliorative effects on the core difficulties of ADHD (Coger et al., 1996).

The notion that elevated rates of smoking among ADHD youth may result, in part, from greater perceived benefits of smoking is consistent with a self-medication hypothesis. However, this is not to suggest that ADHD youth actively and consciously smoke to self-medicate. Rather, it is possible that repeated experiences linking the act of smoking to improved mood and enhanced cognitive states increase the

probability of continued smoking among ADHD youth over time. Indeed, individuals who smoke only one pack of cigarettes per week would have more than 1,000 opportunities per year to associate improved cognitive/affective states with smoking. Stated differently, ADHD youth may have more to gain by smoking than their non-ADHD peers, which may contribute to their increased risk for smoking.

Additional support for the idea of cigarette smoking as a form of self-medication among ADHD youth comes from studies that have linked the severity of ADHD symptomatology to the likelihood and timing of smoking. For example, Burke and colleagues (2001) reported that, among ADHD youth, the greater the number of inattentive symptoms exhibited between ages 13 and 15, the greater the number of days of tobacco use during the same period. Using experience sampling methodology, Whalen and colleagues (2002) reported that relative to adolescents with low levels of ADHD behaviors, adolescents with high levels of ADHD behaviors were 10 times more likely to have smoked and 8 times more likely to have experienced the urge to smoke on an hourly basis. Using survival analysis, Lambert (2002) reported that severity of ADHD symptomatology was associated with an earlier onset of smoking. Finally, although nonsmoking and smoking ADHD adults do not differ in terms of their concurrent reports of ADHD symptomatology, they do differ in terms of their retrospective reports of ADHD symptomatology. ADHD adults who smoke retrospectively report higher levels of ADHD symptomatology in childhood relative to nonsmoking ADHD adults (Conners et al., 1996; O. F. Pomerleau et al., 1995).

Neural and Genetic Coactions

Research on coactions between neural and genetic influences related to ADHD and cigarette smoking is limited. However, an increasing number of studies utilizing molecular genetic methods suggest that ADHD is characterized, in part, by a hypodopaminergic system (Kirley et al., 2002). Decreased levels of dopamine appear to result from polymorphisms of specific dopamine genes that result in increased transporter density, subsensitive dopamine receptors, or atypical synthesis of dopamine (Kirley et al., 2002). Many of these same genes have been implicated in cigarette smoking (Lerman et al., 1998, 1999). Nonetheless, in both cases, individual genetic effects are small, and gene-by-gene interactions are anticipated (Faraone et al., 2001; Lerman et al., 1998, 1999).

Although compelling, these studies currently tell only half of the story. That is, these existing molecular genetic studies characterize individual differences in genes as giving rise to individual differences in neurotransmitter func-

tioning (i.e., genetic \rightarrow neural effects). However, a probabilistic-epigenetic perspective predicts that the reverse is also true. That is, there are likely a variety of experiences (in the broadest sense of the term) that affect gene expression (i.e., neural \rightarrow genetic effects). Although we are not aware of studies that have examined these issues as they pertain to ADHD and cigarette smoking, we point out this omission in the literature to emphasize that, like all levels of analysis, genetic effects should be considered in the context of the larger developmental systems and do not exist in isolation.

Summary

For purposes of organization, we have considered pairs of influence (i.e., environmental-behavioral, behavioral-neural, and neural-genetic coactions) that may increase rates of smoking among ADHD youth. However, a probabilistic-epigenetic perspective posits that all levels of influence work in concert to drive development. This is not to suggest that every level of influence is equally important for every individual at every point in development. Nonetheless, an essential element of the probabilistic-epigenetic perspective (and of systems models in general) is an emphasis on the *coordination* or *coaction* of influences over time. Environmental, behavioral, neural, and genetic influences are best understood in relation to each other. Moreover, individuals are seen as actively working to bring multiple levels of influence into functional alignment (Cairns, 1986).

Adopting this perspective guards against overly simplistic bottom-up (i.e., genetic) or top-down (i.e., environmental) explanations of greater rates of smoking among ADHD youth that will do little to improve our understanding and eventual targeted treatment of this phenomenon. Although a probabilistic-epigenetic perspective is sometimes criticized for being too complex and claiming that everything is related to everything, it should be evident from the studies reviewed that it does not require dramatically different research than is currently done. However, it does require a different integration of existing research, as well as helping to identify areas in the literature in need of greater attention.

Directions for Future Research

In the sections that follow, we consider a number of predictions that result from utilizing a probabilistic-epigenetic perspective to organize the literature on increased rates of smoking among ADHD youth.

Attention-Deficit/Hyperactivity Disorder Subtype Differences in the Likelihood of and Rationale for Smoking

As noted earlier, the *DSM-IV* (American Psychiatric Association, 1994) differentiates ADHD youth into three subtypes based on their primary behavioral presentation: inattentive, hyperactive-impulsive, and combined subtypes. In addition to differing with respect to inattentive and hyperactive-impulsive behaviors, ADHD subtypes also differ with respect to predominant patterns of comorbidity, types of impairment, the nature of their peer relationships, and demographic factors (Carlson, Shin, & Booth, 1999; Lahey, Schaughency, Strauss, & Frame, 1984; Milich, Balentine, & Lynam, 2001).

Building on our earlier review, we predict that ADHD subtypes will experience differential risk for smoking. Specifically, among ADHD youth, we predict that combined-type youth will be at greatest risk for becoming regular smokers, followed by inattentive-type and then hyperactive-impulsive-type youth. This prediction is based on the idea that elevated levels of both hyperactive-impulsive and inattentive symptoms are differentially associated with increased risk for smoking. Whereas inattentive symptoms have a direct effect on increased rates of smoking, hyperactive-impulsive symptoms have an indirect effect. We predict that the direct effect of inattentive symptoms involves self-medication. That is, cigarette smoking is reinforced because it ameliorates the attention problems and negative affect common to ADHD adolescents and adults. In contrast, we predict that the indirect effect of hyperactive-impulsive symptoms results from increased rates of novelty seeking (including a greater propensity and willingness to experiment with cigarettes), as well as increased rates of conduct problems and association with delinquent peers. Among all subtypes, we further predict that greater rates of comorbidity should result in additional risk for smoking. This is consistent with the results of a recent study that reported a linear relationship between the number of comorbid disorders among ADHD youth and their propensity to smoke, though that study did not consider ADHD subtypes (Milberger, Biederman, Faraone, Chen, & Jones, et al., 1997). A related question is whether ADHD subtype differences in the likelihood of smoking are dependent on the persistence of ADHD symptomatology into adolescence and adulthood. There is limited research addressing this topic, and what does exist is equivocal (Molina & Pelham, 2003; C. S. Pomerleau et al., 2003).

In addition to predictions about differential risk for smoking, we also predict ADHD subtype differences in the developmental timing and rationale for smoking. Specifi-

cally, we predict that combined- (and presumably hyperactive-impulsive-) type youth will experiment with smoking at an earlier age than inattentive-type youth. This difference will be mediated by elevated rates of novelty seeking and involvement with delinquent peers. At least initially, the rationale for smoking among these individuals will be due more to perceived peer status and experimentation than self-medication. In contrast, we predict a later initiation of smoking among inattentive-type youth and a rationale for smoking that is less related to peer status and experimentation and due more to self-medication (e.g., improved concentration and enhanced mood).

There are broad parallels between our predictions and a recent motivational model of risky behaviors. Briefly, M. L. Cooper and colleagues (M. L. Cooper, Agocha, & Sheldon, 2000) recently reported that whereas the association between neuroticism (heightened emotional lability, self-doubt, negative rumination) and risky behaviors was partially mediated through aversive motivational processes that were intended to reduce negative emotional states, the association between extraversion and risk behaviors was mediated through appetitive processes that were intended to increase positive affect. Moreover, consistent with their predictions, these associations were moderated by impulsivity. We believe that there are broad similarities between aspects of extraversion and externalizing disorders that typically co-occur with combined-subtype ADHD youth, as well as similarities between aspects of neuroticism and internalizing disorders that typically co-occur with inattentive-subtype ADHD youth. Consideration of personality dimensions (extraversion, neuroticism) that are at least conceptually similar to comorbid diagnoses (Oppositional Defiant Disorder, Conduct Disorder, depression, anxiety) is also appealing given that the former deal more explicitly with emotion and emotion regulation, which is an area that has received limited attention in the ADHD literature (Melnick & Hinshaw, 2000; Peris & Hinshaw, 2003).

Self-Reports of Attention-Deficit/Hyperactivity Disorder Associated with the Onset of Regular Smoking

In childhood, parents and teachers are considered optimal informants of ADHD symptomatology (Loeber, Green, Lahey, & Stouthamer-Loeber, 1989; Power et al., 1998). However, with the transition to adolescence and adulthood, reliance on parent and teacher reports of ADHD symptomatology becomes more difficult. For example, changes in schooling result in individual teachers spending a smaller amount of time with students than was the case in elementary school settings. Moreover, adolescents increasingly spend greater periods alone or with peers than with par-

ents. The result is that parents and teachers have diminished opportunities to observe and interact with youth, making them potentially poorer informants of ADHD symptomatology.

Given these changes, researchers have frequently relied on adolescent and adult self-reports of their own ADHD symptomatology for assessment purposes. Initially, it was hoped that ADHD youth would possess greater levels of self-insight as adolescents and adults and, as a result, become better informants of their own ADHD symptomatology (Conners, 1985). Nonetheless, although the use of adolescent and adult self-reports of ADHD symptomatology has become widespread, they are often only marginally related to other (e.g., parent) reports (Barkley, Fischer, Smallish, & Fletcher, 2002; Mannuzza, Klein, Klein, Bessler, & ShROUT, 2002; Smith, Pelham, Gnagy, Molina, & Evans, 2000).

Although discrepancies between self- and other reports of ADHD symptomatology represent a challenge when making diagnoses of ADHD in adolescence/adulthood, this discrepancy may help inform questions about cigarette smoking. Specifically, to the extent that elevated rates of cigarette smoking among ADHD youth relate to a self-medication hypothesis, individuals with high levels of *self-reported* ADHD (particularly inattentive) symptomatology should be more likely to smoke than individuals with high levels of *other-rated* ADHD symptomatology. This stems from an assumption that at least a subset of ADHD youth smoke in an effort to alleviate subjective experiences of distress (e.g., anxiety, depression) and/or the concomitant impairments that result from attention deficits (e.g., poor academic or occupational performance). Consistent with this prediction, Whalen and colleagues (2002) reported that elevated levels of self-reported ADHD symptomatology were more strongly related to both the urge to smoke and to actual smoking than were elevated levels of parent-rated ADHD symptomatology. Moreover, the subset of adolescents with elevated rates of ADHD symptomatology according to both self- and parent report exhibited the highest likelihood of smoking and the urge to smoke (Whalen et al., 2002).

Cigarette Smoking Should Alter the Developmental Course of Inattentive but Not Hyperactive-Impulsive Symptoms Over Time

Although ADHD is currently considered a lifelong chronic disorder, ADHD symptomatology decreases over time for a large number of diagnosed youth, with hyperactive-impulsive behaviors diminishing more rapidly than inattentive behaviors (Biederman, Mick, & Faraone, 2000; E. L. Hart,

Lahey, Loeber, Applegate, & Frick, 1995). Given that cigarette smoking ameliorates inattentive but not hyperactive-impulsive symptoms, we predict that the emergence of regular smoking should alter the rate of change among inattentive, but not hyperactive-impulsive, symptoms over time (see also Conners et al., 1996). Specifically, after controlling for individual differences in the severity of ADHD, we predict that relative to nonsmoking ADHD youth, the initiation of smoking will result in time-specific reductions in inattentive, but not hyperactive-impulsive, symptoms and that emergence of regular smoking will accelerate the rate of decline in inattentive but not hyperactive-impulsive symptoms over time. Given indication that severity of inattentive symptomatology is predictive of future smoking, evaluating this prediction will necessitate matching or controlling for ADHD (primarily inattentive) symptom severity prior to testing whether smoking onset results in greater reductions to inattentive versus hyperactive-impulsive symptoms.

Psychostimulant Treatment Should Buffer against the Onset of Cigarette Smoking

Many of our predictions build on the idea that the adoption of regular smoking (not necessarily early experimentation) among ADHD youth occurs, in part, because it is perceived as beneficial. This assumption could be evaluated by examining the rates of smoking among ADHD youth who are receiving treatment. We predict that individuals who are receiving treatment for ADHD, especially pharmacological treatments that influence the catecholamines, should be less likely to smoke regularly, because their attention deficits should be less salient to them. Similarly, ADHD youth who have comorbid disorders that are associated with subjective feelings of distress (e.g., anxiety, depression) and who are being treated for these disorders should also be less likely to smoke (relative to peers who are not receiving treatment for comorbid conditions).

Previous studies concerning this prediction are equivocal. In support of our prediction, Whalen and colleagues (Whalen, Jamner, Henker, Gehricke, & King, 2003) recently reported that medication treatment among ADHD youth was associated with reduced rates of tobacco use. Specifically, in the context of a community-based longitudinal study, relative to unmedicated ADHD youth, medicated ADHD youth were less likely to have experimented with smoking, to be current smokers, or to have urges to smoke. In addition, over a 2-year window between freshman and sophomore years of high school, levels of salivary cotinine, a biomarker of nicotine intake, increased for un-

medicated ADHD youth but not medicated ADHD youth (Whalen et al., 2003).

Loney and colleagues (Loney, Kramer, & Salisbury, 2002) extended the results of the Whalen study into adulthood. Specifically, in a longitudinal follow-up of clinic-referred ADHD youth who were assigned to psychiatrists with different treatment preferences (medication versus psychosocial), medication treatment in childhood was associated with decreased rates of smoking and other stimulant use in adulthood. In addition to the pseudo-random assignment of children to treatment condition, Loney et al. also controlled for initial levels of ADHD, which reduced the likelihood that their results were confounded by severity levels of ADHD.

Equivocal support for our prediction came from a study by Biederman and colleagues (Biederman, Wilens, Mick, Spencer, & Faraone, 1999). In their study, ADHD youth who were treated with psychostimulants had a decreased likelihood of substance use disorders at follow-up; however, the protective effect associated with psychostimulant treatment did not extend specifically to tobacco use. In contrast to our prediction, Lambert (2002; Lambert & Hartsough, 1998) reported that ADHD youth who were treated with medication were *more* likely to smoke from late adolescence into early adulthood than were ADHD youth who were not treated with medication. Lambert and colleagues' results are interesting in light of an incentive-sensitization theory of addiction (Robinson & Berridge, 2000). Briefly, although based primarily on animal literature, it is conceivable that prolonged pharmacological (psychostimulant) treatment of ADHD in childhood could result in "neuroadaptations in dopamine circuitry" that would increase the probability of regular smoking in adolescence or adulthood (Robinson & Berridge, 2000). Although theoretically compelling, there is no research to directly inform this question.

Resolving discrepancies between these studies is difficult, in that they differ in terms of referral source/recruitment strategy, method of diagnosis, sample size, control of confounding variables, and measures of tobacco use. Moreover, three of the four studies are limited by the use of observational designs. A more rigorous test of whether medication treatment protects against the initiation and maintenance of smoking would involve the random assignment of ADHD youth to treatments that varied with respect to medication use (e.g., placebo/wait list versus psychosocial-only versus medication-only treatment). Randomized treatment studies would eliminate confounds to existing studies (e.g., severity of ADHD symptomatology, psychiatric comorbidity). Given its large sample and random as-

signment of participants to treatment condition, the National Institute of Mental Health Collaborative Multimodal Treatment Study of Attention-Deficit/Hyperactivity Disorder (MTA) study (Arnold et al., 1997; Richters et al., 1995) would provide an excellent test of whether pharmacological treatment protects against the initiation of regular smoking.

It is noteworthy that cigarette smoking may serve beneficial effects with respect to cognitive deficits and affective distress even in the presence of treatment with psychostimulants. To this end, Levin and colleagues (2001) argued that whereas methylphenidate inhibits the reuptake of monoamines, nicotine potentiates their release. Thus, it is conceivable that cigarette smoking and psychostimulant treatment may play additive roles in the treatment of ADHD. Nonetheless, a small study of 40 nonsmoking ADHD adults who were randomly assigned to treatments involving nicotine, methylphenidate, their combination, or a control condition did not provide support for this alternative hypothesis (Levin et al., 2001).

Genetic Markers as Moderators of Previous Predictions

To this point, our predictions have emphasized the environmental, behavioral, and neural influences that may account for increased rates of smoking among ADHD youth. Throughout this example, we have alluded to the idea of smoking as a form of self-medication for at least a subset of ADHD youth. Implicit in the self-medication argument is the idea that there are individual differences among ADHD youth in both the experience of cognitive deficits and affective distress and in the effectiveness of smoking to alleviate these deficits/distress. One way cigarette smoking may ameliorate difficulties associated with ADHD is through changes in the catecholamines.

Although in their infancy, molecular genetic studies of both ADHD and smoking suggest that polymorphisms associated with dopamine genes are associated with individual differences in synaptic dopamine levels. These individual differences in synaptic dopamine levels may contribute to individual differences in the decision to smoke, the subjective appraisal of the value of smoking, and the likelihood of continuing to smoke. This suggests that many of our previous predictions may be moderated by individual differences in polymorphisms of specific dopamine genes. For example, predictions about increased rates of smoking due to elevated levels of inattentive symptomatology or decreased rates of smoking due to pharmacotherapy may be moderated by individual genotypes/polymorphisms. Incorporating information about individ-

ual differences in polymorphisms for different dopamine genes into studies that examine the increased risk of smoking among ADHD youth may provide a strategy for incorporating molecular genetic studies into the broader literature in a way that is consistent with the organizing principles of a probabilistic-epigenetic perspective (see, e.g., Rohde et al., 2003; Winsberg & Comings, 1999). Just as it is insufficient (incomplete) to rely on solely genetic explanations for increased rates of smoking among ADHD youth, it is equally insufficient to rely exclusively on environmental, behavioral, and neural explanations to account for this association.

Linkages between Probabilistic Epigenesis and Prevention and Resilience

In the previous sections, we considered some of the obstacles that interfere with a greater adoption of probabilistic epigenesis in individual research. We also used probabilistic epigenesis to organize existing research on elevated rates of cigarette smoking among ADHD youth, as well as to identify directions for future research. In this final section, we briefly consider how a probabilistic-epigenetic perspective relates to two major themes in developmental research: prevention science and the study of risk and resilience.

Probabilistic Epigenesis and Prevention

Figure 17.1 provides a concise summary of a probabilistic-epigenetic perspective. Arguably, the most important feature of this perspective is a reliance on the idea of coactions to explain how and why development happens (Gottlieb & Halpern, 2002). Horizontal and vertical coactions refer to the relationship within and between each of the levels of influence depicted in Figure 17.1. The concept most frequently used to designate coactions at the organismic level of functioning is experience, which is used in the broadest sense of the word. Experience includes everything from the “electrical activity of nerve cells” to “neurochemical and hormonal secretion” to “the behavior of the organism” (Gottlieb, Wahlsten, & Lickliter, 1998, p. 242). From a probabilistic-epigenetic perspective, experience is said to play facilitative, inductive, and maintenance functions (Gottlieb, 1976, 1992).

Facilitative experience refers to processes that enhance the likelihood of the outcome, thus influencing the developmental timing or age of onset of a particular outcome. *Inductive* experience refers to changes in an organism that would not normally occur had the organism not had a particular experience. *Maintenance* experience refers to events

and processes that serve to sustain an achieved organismic outcome. Figure 17.8 depicts the relationship among facilitative, inductive, and maintenance experiences. Unfortunately, developmental studies often do not specify the different roles that experience plays in development. Next, we suggest how the different roles of experience might relate to three different types of prevention.

Over the past decade, prevention science has flourished (Durlak & Wells, 1997; Koretz & Moscicki, 1997). Prevention trials have been categorized into universal, selective, and indicated programs (Mrazek & Haggerty, 1994). The primary distinction between different models of prevention concerns the targeted population. Whereas universal programs target an entire population, selective preventive interventions target subgroups of the general population that are at higher risk for developing a problem than other members of the broader population, and indicated preventive interventions target individuals who have detectable signs or symptoms of difficulty but not long-standing serious problems or full-blown clinical disorders.

As others have noted, a reciprocal relationship exists between prevention trials and developmental theory. In short, theoretically derived models of the developmental processes implicated in the emergence of dysfunction are necessary before prevention programs can be implemented. In turn, prevention trials address fundamental causal processes and can be used to experimentally test questions about the etiology of dysfunction (Cicchetti & Toth, 1992; Coie et al., 1993). We believe that the combination of the emphasis of probabilistic epigenesis on the three different functions of experience (facilitative, inductive, and maintenance) with the three different types of prevention trials (universal, se-

Figure 17.8 Developmental sequence of inductive, facilitative, and maintenance experiences with respect to the etiology of ADHD. If inductive experience is not followed by maintenance experience, the induced outcome may wane. Facilitative experiences act to accelerate the onset of the outcome of the inducted experience (e.g., if one has friends who smoke that may facilitate the onset of smoking).

lected, indicated) provides a means for delineating the *sets of experiences* associated with particular developmental outcomes in ways that have not been fully capitalized on to date.

In keeping with our extended example, we assume that there are facilitative experiences that increase the probability that ADHD youth will smoke, that in some cases these are followed by inductive experiences associated with the start of regular smoking, and that there are maintenance experiences that will serve to keep ADHD youth smoking, once started, on a daily basis. If we define the population of interest as ADHD youth and the developmental outcome of interest as the initiation of daily smoking, direct treatment of ADHD symptomatology may serve as a universal prevention because ADHD symptomatology facilitates smoking. An antismoking program directed to the families whose child is receiving treatment for ADHD may serve as a selective prevention because parental and sibling smoking serve an inductive process, through modeling and the availability of cigarettes. Finally, a coping skills-based program designed to provide ADHD adolescents with appropriate strategies for managing life stress and/or negative affect may serve as an indicated prevention because smoking to cope with interpersonal stress or negative mood serves as a maintenance experience. We could randomly assign ADHD youth to varying levels of prevention (e.g., universal-only, universal+selected, universal+selected+indicated). To the extent that the rates of daily smoking were reduced in the universal+selected and universal+selected+indicated groups relative to the universal-only group, this would provide support for the roles of inductive (familial smoking) and maintenance (smoking to cope with interpersonal stress or negative mood) experiences targeted. Of course, other processes implicated in the emergence of daily smoking could be targeted (e.g., peer group interventions). Our goal is simply to highlight the correspondence between different types of prevention and the different roles that experience plays within the probabilistic-epigenetic framework.

Probabilistic Epigenesis and Resilience

Similar to prevention science, the scientific study of resilience has seen substantial progress over the past 2 decades (Luthar, 2003; Masten, Best, & Garmezy, 1990). Resilience has been defined as a “dynamic process encompassing positive adaptation within the context of significant adversity” that implicitly requires exposure to a threat or adversity and the achievement of positive adaptation (Luthar, Cicchetti, & Becker, 2000, p. 543). Historically, the study of resilience has been primarily restricted to psychosocial/behavioral levels of analysis. However, there is a

growing appreciation that biological processes (genetic and neural levels of influence, in the probabilistic-epigenetic framework) should be integrated into the study of resilience (Curtis & Cicchetti, 2003). This broadening of scope makes the study of resilience more consistent with a probabilistic-epigenetic perspective.

There are two features of the study of resilience that pertain to our extended example. First, resilience is considered a process, not a characteristic of an individual. We strongly believe that process-oriented research is necessary to understand elevated rates of smoking among ADHD youth. Second, the study of resilience orients researchers to think about positive adaptation. Many of the topics developmentalists study are inherently negative (conduct problems, peer rejection, school dropout, etc.). The study of resilience orients researchers to focus not simply on avoidance of negative outcomes, but also on the achievement of positive outcomes. This is consistent with a broader organizing goal of developmental psychopathology, in which the study of normal populations is intended to inform the study of abnormal populations and vice versa (Cicchetti, 1984).

Considering resilience as it pertains to our extended example, an important future goal will be to describe the characteristics and experiences of ADHD youth who do experiment with and/or initiate regular smoking relative to those who do not. For example, it is conceivable that non-smoking ADHD youth differ from their smoking counterparts in terms of characteristics specifically related to smoking (e.g., concern with physical health) or in terms of more general coping strategies for managing their ADHD symptomatology and its negative sequelae (e.g., academic and occupational problems). In addition, given heterogeneity in the neuropsychological deficits that characterize ADHD youth (Sonuga-Barke, 2002), it will be important to explore whether there are distinct neuropsychological profiles that mediate or moderate smoking outcomes. Once again, our goal is not to make specific recommendations. Rather, it is to suggest that a probabilistic-epigenetic perspective is consistent with the scientific study of resilience in focusing on positive outcomes (adaptation), not simply the avoidance of negative outcomes.

CONCLUSION

Developmental psychopathology is a new discipline. In the 2 decades since its formal inception, there has been a veritable explosion of research on all forms of psychopathology. An ongoing challenge to the field is the integration of

research from a variety of disciplines in a way that promotes a cumulative and comprehensive understanding of individual disorders. Probabilistic epigenesis provides a framework for accomplishing this task.

Critics frequently charge that the complexity of probabilistic epigenesis undermines individual efforts to engage in empirical research. This is inaccurate. Although individual researchers who adopt a probabilistic-epigenetic perspective consider their substantive questions from multiple perspectives, there is no expectation that any single researcher will specialize in all levels of analysis. Rather, multidisciplinary collaborations are emphasized. Moreover, individual studies are not expected to measure and/or relate all levels of influence. However, simultaneous consideration of two levels of influence represents an enormous improvement over current research that frequently relies on either environmental or genetic explanations of developmental phenomena.

Throughout this chapter, we have considered some of the obstacles that interfere with a greater adoption of probabilistic epigenesis in individual research. We have also used probabilistic epigenesis to organize existing research on elevated rates of cigarette smoking among ADHD youth, as well as to create testable predictions for future research. Through these efforts, we hope to promote greater reliance on a probabilistic-epigenetic perspective among researchers in their individual research pursuits. We believe that the epistemological superiority of developmental systems thinking has already taken root in multiple disciplines. For examples that have been explicitly informed by the concept of probabilistic epigenesis, see reviews of psychopathology by Cicchetti and Cannon (1999) and Cicchetti and Tucker (1994); neuroscience by Johnson (1999); psycholinguistics by Shanker (2002); and developmental systems theory itself by Molenaar, Huizenga, and Nesselrode (2003). The ongoing challenge is to distill the ideas common to modern developmental metatheory in a way that guides individual research studies.

GOALS OF THE CHAPTER

Developmental psychopathology, once the Cinderella of perspectives on mental health even in child psychiatry, has over the past 2 decades become the dominant approach to the study of mental disorder. Emerging findings from longitudinal studies consistently demonstrate that two-thirds to three-fourths of psychological disorders in adulthood are anticipated by childhood psychiatric disturbance (e.g., Kim-Cohen, Caspi, Moffitt, Harrington, & Milne, 2003). This establishes beyond doubt that only a developmental perspective can possibly provide a comprehensive understanding of the nature of mental disorder and offer sufficient information for adequate treatment and prevention.

Psychoanalysis, for better or worse, has exerted considerable influence on developmental psychopathology. Many influential figures in the field of developmental psycho-

pathology received a psychoanalytically orientated clinical training, and others were sympathetic to psychoanalytic ideas. Yet, others were keen to identify crucial differences between the analytic tradition and developmental psychopathology. Psychoanalysis, with its unique if controversial epistemology, continues to have the potential to inform research in developmental psychopathology. The present chapter aims to provide a historical overview of the psychoanalytic approach, taking a dual developmental perspective. We outline the emergence of analytic ideas and the changing assumptions and emphases of the key perspectives between Freud's original discoveries and the present day. In offering this historical overview, we aim to emphasize the contribution that psychoanalytic ideas can make to a developmental understanding of the emergence of psychological disturbance. We critically appraise as well as highlight the contribution of the approaches we consider and evaluate

them wherever possible in the context of pertinent empirical evidence. As psychoanalytic formulations were intended to be evaluated in terms of evidence emerging from individual psychotherapeutic treatments rather than systematic empirical studies, often the link to empirical data is suggestive rather than definitive. Nevertheless, we place great emphasis on attempts to make such links in the hope of ensuring that psychodynamic formulations will continue to play a part in theory building and the construction of research questions in the future of this now mature discipline.

THE CENTRAL PLACE OF DEVELOPMENT IN PSYCHOANALYTIC THEORY

Psychoanalysis is all about children. When Sigmund Freud conceived of his “neurotica” he already had a model in mind fundamentally inspired by embryology. When the contemporary analyst addresses unreasonable relational expectations and disturbing preconscious fantasies with her patient, the assumption that she is focusing on childlike modes of thinking runs right through the interaction. The key idea, unchanged since Freud’s day, is the notion that pathology is rooted in and in critical respects made up of recapitulated ontogeny. Disorders of the mind are best understood as maladaptive residues of childhood experience, developmentally primitive modes of mental functioning. The developmental point of view is acknowledged by all genuinely psychoanalytic theories to some degree.

For Freud (see S. Freud, 1905/1960, 1914/1957, 1926/1959; S. Freud & Breuer, 1895/1955), the developmental point of view implied that personality types and neurotic symptoms could be linked with specific developmental stages, and that symptoms could be understood in terms of fixations at and regressions to earlier periods of normal development. In Freud’s thinking, there was an apparent reversibility between childhood and psychopathology. For example, Freud’s theory of narcissism or self-development during infancy was invoked to explain adult psychosis, and conversely, his view of psychic life during infancy was constructed largely on the basis of observations of adult psychopathology. His notion of infantile grandiosity is derived from the grandiosity observed in many instances of psychosis. The presumed confusion, presumed hallucinatory experiences, and lack of reality testing of Freud’s infant seem to parallel psychotic experiences.

Alternative clinical foci proposed in accounts of psychological disturbance by contemporary followers of Freud were also based on developmental formulations: Alfred Adler (1916) focused on the child’s feelings of inferiority to explain the adult’s striving for power and maturity; Ferenczi (1913) wrote of the child’s conflicts in developing a

sense of reality as it entailed the simultaneous sacrifice of fantasized omnipotence; Rank (1924) considered the earliest trauma, that of birth, to explain many subsequent human conflicts, defenses, and strivings. More recent psychoanalytic theories continued the developmental motif. Anna Freud (1965) provided a comprehensive model of psychopathology based on the dimensions of normal and abnormal personality development. Melanie Klein (1930, 1935/1984a) offered a radically different perspective both on severe mental disorders and on early child development. Hartmann, Kris, and Loewenstein (1946) focused on the evolution of mental structures necessary for adaptation and elaborated on the common developmental conflicts between mental structures in early childhood. Among the French psychoanalysts, Laplanche (1989) brought a coherent developmental perspective to the emergence of sexuality in infancy. Mahler and her colleagues (Mahler, Pine, & Bergman, 1975) provided a dynamic map of the first 3 years of life and framed a model for the developmental origins of personality disorders. Fairbairn (1952) traced the development of object seeking from immature to mature dependence; E. Jacobson (1964) explored the development of representations of self and other. Kernberg (1975) drew on previous work by M. Klein, Hartmann, and Jacobson to furnish a developmental model of borderline and narcissistic disturbances; Kohut (1971, 1977) constructed a model of narcissistic disturbances based on presumed deficits of early parenting. Relational theorists (e.g., Davies, 1998; S. A. Mitchell, 2000) brought their unique emphasis on active transactional processes to child development, seeing more clearly the parents’ unconscious contributions.

Notwithstanding the importance of the developmental perspective for all these theories, the application of knowledge from child development to theorization is centrally flawed by at least two related difficulties. The first concerns unjustified confidence in tracing psychopathology of particular forms to specific phases (an example is the link made between Borderline Personality Disorder and the rapprochement subphase of separation and individuation). The second relates to the overemphasis on early experience, which is frequently found to be at odds with developmental data. Westen et al. (1990a, 1990b) are particularly clear in their evidence that pathological processes of self-representation and object relationships actually characterize developmental phases far later than those that have traditionally concerned psychoanalytic theoreticians. The emphasis on deficits in preverbal periods is a particular problem for psychoanalytic theory because it places so many of the hypotheses beyond any realistic possibility of empirical testing.

Peterfreund (1978) pointed out that there were problems with “adultomorphising infancy,” which he felt was a domi-

nant tendency in psychoanalytic developmental theory. This was the tendency to use hypotheses about later states of psychopathology to describe early stages of development. Certainly, if an adult behaved as an infant does, he or she could be described as being in a state of fusion, narcissism, omnipotence, Autism, symbiosis, or as being disoriented and as having hallucinatory experiences and delusions. But logically untenable accounts are produced if an adult-oriented system is used to describe the infant's functioning given his or her limited behavioral possibilities. Some of the regressive manifestations associated with psychosis have no real counterpart in normal development. It has been pointed out that we cannot know what the infant experiences (Stechler & Kaplan, 1980). Thus, it is hard to see how empirical evidence in support of psychoanalytic claims can ever be compiled (A. Green, 2000; Wolff, 1996). Clinically based developmental accounts also tend to mirror the metapsychological commitment of the author to, for example, a drive versus an object relationship-based theory (compare the accounts of Anna Freud and Melanie Klein). Psychoanalytic metapsychology is anyway at best loosely coupled to clinical observations (Gill, 1976; Holt, 1976; G. S. Klein, 1976b; Schafer, 1976), and so it cannot provide an independent test of developmental theory.

Identifying what appear to be childlike modes of mental functioning in individuals with severe disorders, such as Borderline Personality Disorder or Schizophrenia, cannot be taken as evidence for the persistence or regressive recurrence of early pathogenic experiences. Even if putative pathogenic mechanisms such as horizontal splitting (Kohut, 1971) or identity diffusion (Erikson, 1956; Kernberg, 1967) in some way represented early modes of thought, this in no way implies that their reemergence in adult mental functioning is indicative of a developmental timetable. For example, infantile modes of cognition may be evoked in relation to later rather than earlier trauma (Fonagy, 1996). In a review of psychoanalytic theorization about Schizophrenia, Willick (2001) provided a number of current examples from the literature that illustrate that this criticism applies not only to past psychoanalytic theory but also to some work being done today. The general lack of sophistication concerning the process of development in psychoanalysis, the subtle intertwining of phase-specific processes, the qualitative leaps forward as emergent integration brings fresh ways of seeing the world within the grasp of the child, is probably part of a broader epistemic problem that restricts legitimate psychoanalytic theorization to a phenomenon accessible to the analyst through transference and countertransference. There are cogent arguments against the wholesale integration of studies of infant behavior into psychoanalytic theory (A. Green, 2000;

Wolff, 1996). However, by distinguishing between content and mechanism, representation and process (Fonagy, Moran, Edgcumbe, Kennedy, & Target, 1993), we can make excellent use of developmental data to deepen our psychoanalytic understanding of psychological disturbance.

Recent longitudinal, epidemiological birth cohort studies have provided dramatic confirmation that psychoanalysts were on the right track when they emphasized the developmental perspective in their understanding of the clinical problems they faced with their adult patients (Hofstra, van der Ende, & Verhulst, 2002; Kim-Cohen et al., 2003). These studies show that in the vast majority of cases, adult psychopathology is antedated by diagnosable childhood disturbance. Across adult disorders, 75% had a diagnosable childhood problem (Kim-Cohen et al., 2003). It is impossible to conceive of adult problems without considering the development of vulnerabilities, biological and psychosocial, that antedate the disturbance. In fact, there seems to be no other realistic way of thinking of psychopathology other than developmentally (Munir & Beardslee, 1999). However, this only makes the task of examining the status of psychoanalytic theorization from a developmental perspective all the more urgent. In this chapter, we explore the developmental aspects of the major theoretical traditions within psychoanalysis.

FREUD AND THE ESTABLISHMENT OF THE DEVELOPMENTAL PSYCHOANALYTIC TRADITION

Freud's move away from his seduction hypothesis in favor of his second model, which emphasized fantasy determined by the biological drive state, took his attention away from social determinants of development and mental disorder. It led him (S. Freud, 1905/1953) to try to explain all behavior in terms of the failure of the child's mental apparatus to deal adequately with the pressures inherent in a maturationally predetermined sequence of drive states. Adult psychopathology, dreaming, jokes, and slips of the tongue were all seen as the revisiting of unresolved childhood conflicts over sexuality (S. Freud, 1900/1966, 1901/1960, 1905/1960). Freud was the first to give meaning to mental disorder by linking it to childhood experiences (S. Freud & Breuer, 1895/1957) and to the vicissitudes of the developmental process (S. Freud, 1900/1966). One of his greatest contributions was undoubtedly the recognition of infantile sexuality (R. Green, 1985). Freud's discoveries radically altered our perception of the child from one of idealized innocence to that of a person (S. Freud, 1933/1964) struggling to achieve control over his or her biological needs and make them acceptable to society through the microcosm of his or her family (S. Freud, 1930/1961).

S. Freud's (1920/1955, 1922/1961, 1926/1959) third major shift in thinking once again gave a prominent place to the influence of the social environment in analytic theory. This new structural theory long outlasted Freud. In particular, the dual instinct theory provided a compelling fit with clinical observational data (S. Freud, 1920/1955). For example, full recognition was given to the significance for psychopathology of the child's struggle with innate destructive and self-destructive forces (the "death instinct"). S. Freud (1926/1959) also at this time revised his view of anxiety. He now saw it as a psychological state linked to the perception of internal (instinctual or moral) or external danger rather than an epiphenomenal experience associated with inhibited biological drives. The fear of helplessness resulting from loss (loss of the mother, of her esteem, loss of a body part, or loss of self-regard) was specified as the danger situation. This revision recast the theory in more cognitive terms (Schafer, 1983), restoring adaptation to the external world as an essential part of the psychoanalytic account. S. Freud (1926/1959, p. 162) nonetheless retained the concept of a more primitive form of anxiety that would arise in an involuntary, automatic way "whenever a danger situation analogous to birth" occurred. It is this automatic pervasive anxiety and the associated state of overwhelming helplessness that is warded off with the help of "signal anxiety." This prompts the ego to limit the threat of a basic danger situation (see Yorke, Kennedy, & Wiseberg, 1981).

Some developmental evidence supports the central role Freud gave to anxiety in the context of the structural model. Although not a universal finding, the pattern of depression preceded by anxiety occurs sufficiently often to emphasize the fundamental nature of anxiety for psychological disorders. For example, Anxiety Disorder precedes recurrent familial Major Depression in adulthood in most cases (Warner, Weissman, Mufson, & Wickramaratne, 1999). The opposite pattern of depression leading to anxiety has not been seen as a developmental pattern (Zahn-Waxler, Klimes-Dougan, & Slattery, 2000).

This final revision in Freud's thinking resulted in a developmental framework based around the tripartite structural schema of id, ego, and superego (S. Freud, 1922/1961, 1933/1964, 1940/1964). The hypothesis that conflicts within the human mind is chiefly organized around three themes—(1) wish versus moral injunction, (2) wish versus reality, and (3) internal reality versus external reality—has had extraordinary explanatory power. Notably, the ego's capacity to create defenses became the cornerstone of psychoanalytic theorization and clinical work in the United States (Hartmann et al., 1946) and Britain (A. Freud, 1936).

There are many limitations to Freud's developmental model. The many later elaborations of psychoanalytic theories bear testament both to cultural differences in psychological theory and the need of subsequent theorists to make their own contributions. It can be argued that the most important post-Freudian contributions have been in the domains of the cultural and social contexts of development; the significance of early childhood experiences; the developmental significance of the real behavior of the real parents; the role of dependency, attachment, and safety in development alongside the role of instinctual drives; the synthesizing function of the self; and the importance of the nonconflictual aspects of development. Freud's contemporaries pointed out many of these shortcomings, frequently moving away from organized psychoanalysis under a cloud (at least as far as Freud was concerned). Their association with these themes, along with their distancing from psychoanalysis, may have delayed general consideration of their ideas within organized psychoanalysis. For example, Jung's (1912, 1916, 1923) rejection of libido theory led to a neglect of his undoubted advances in the understanding of narcissism and his development of a theory of the self throughout the life cycle.

The picture concerning empirical evidence for Freud's developmental model is not as bleak as many critics think (e.g., Crews, 1996; Webster, 1995). Westen (1998; Westen & Gabbard, 2002a, 2002b) demonstrated that there exists substantial empirical support for Freud's core construct: that human consciousness cannot account for its maladaptive actions. A similar position has been adopted by the outstanding neuroscientist and Freud scholar Mark Solms (1997a, 1997b). There is good evidence for Freud's basic proposition that much of complex mental life is not conscious, that people can think, feel, and experience motivational forces without being aware of them and can therefore also experience psychological problems that they find puzzling. Freud's claim that unconsciously we are in some ways capable of more complex mental operations is supported by literally thousands of research findings, even if the unconscious that such studies point to is composed of processing structures that share little with Freud's original postulate of nonconscious mentation (Kihlstrom, 1987). There is an extensive literature on nonconscious priming, where words are presented briefly, followed by ambiguous stimulus (e.g., the word "bank" when preceded by the word "river" would cause participants to interpret it as a river bank). The interpretation of the ambiguous stimulus could be biased by the prime, even if the participant was not aware of having seen or heard it (Marcel, 1983a, 1983b). Participants in another experiment who were asked to com-

pose a ballad after hearing a series of ballads could follow double the number of rules of ballads in their composition compared to rules they could consciously articulate (Rubin, Wallace, & Houston, 1993).

Much current cognitive science research is focused on how memory can determine behavior implicitly, rather than through remembering a particular episode. Work on procedural, or implicit, memory demonstrates that we act in certain ways because of experience, despite our inability to recall those particular experiences (e.g., Squire & Kandel, 1999). Milner, Squire, and Kandel (1998) describe not one but five memory systems that retain information about experience without conscious knowledge of the experiences that led to the registration of the memories. They are neurologically distinct in location. Thus, whereas explicit memory is underpinned by the hippocampus and related structures, emotional responses are encoded in the neocortex and priming biases in perception are mediated by the sensory neocortex. The separateness of these systems is borne out by lesion studies. Ample evidence is available from research on brain damage that processing relevant to emotional experience can take place outside awareness. An example is an experiment where individuals with hemifield neglect (consistently ignoring one half of the visual field) were presented with two pictures of a house. In one picture, the house was depicted as on fire in the half of the visual field of which they had no awareness (Halligan & Marshall, 1991). The patients could not detect and failed to report a difference between the house that was on fire and the house that was not. Nevertheless, they all said they would prefer to live in the house that was not depicted as being on fire. From a developmental point of view, it is essential that we appreciate that implicit procedural memories are formed from the earliest time, whereas episodic declarative memory processes mature slowly (Nelson, 1993). It follows from this that early childhood experiences are likely to be “remembered” in the sense of implicitly influencing behavior. Yet the experiences that have led to these memories are forever lost. The classical illustration of this process is Claparde’s patient who suffered from Korsakoff’s syndrome. As is well-known, as part of a demonstration, Claparde shook hands with his patient, pricking her with a pin hidden in his hand. The patient, though having no conscious memory of the experience, declined to shake hands with him the next day. She was aware of her fear of him, but not of the reason why. We can understand this all too well from a neuroscience perspective. The amygdala, unlike the hippocampus, rarely forgets, is implicit, is impressionistic rather than accurate, is nonconscious, and is augmented rather than inhibited by cortisol

(LeDoux, 1996). Thus, although early childhood trauma is unlikely to be remembered because of the immaturity of the memory system, the impact of stress on the functioning of the hippocampus at the time of that experience may affect memory functioning because of the impact of stress hormones on the neural structures underpinning memory. Freud’s original observations of the absence of an explicit memory in the presence of emotional remembering may be an artifact of such neuropsychological constellations.

There are many other similarities between Freud’s theory of affect and modern ideas such as those of Damasio (1999), LeDoux (1995, 1999), and Panksepp (1998, 2001; for a review of this work, see Westen & Gabbard, 2002a, 2002b). Such “verification” of the psychoanalytic model is in itself fascinating, but knowledge of brain-mind relations are not yet at the point where verification is realistic. Solms and Nersessian (1999, p. 91) themselves admit that “a psychological model only becomes accessible to physical methods of investigation once the neural correlates of the components of the model have been identified.” Particularly lacking is detailed knowledge of the developmental changes in neural substrates or psychobehavioral manifestations of specific emotion systems that could enable such direct translations (see Panksepp, 2001). The time will come when Freud’s model will be judged against the discoveries of neuroscience. Until then, consistency with experimental and developmental psychological observations is an important and appropriate aim.

THE STRUCTURAL APPROACH

The dominant psychoanalytic model in the United States during much of the second half of the past century was the so-called structural model. The term derives from Freud’s emphasis on delineating the three psychic structures of id, ego, and superego, and attempting to explain mental disorder as conflicts between these agencies. Within the structural model, the structure of the ego is emphasized over id and superego and mental disorder is seen partially as a failure of adaptation to internal and external conflict.

The Repositioning of Development in Psychoanalysis

The *ego psychological approach* represents an essential repositioning of psychoanalytic developmental ideas. A dominant tradition of North American psychoanalysis extending over a 60-year period, it is impossible to provide an adequate summary of the many complex ideas to emerge

from this school. Our focus is on the key advances of relevance to the developmental perspective and their implications for a model of psychopathology.

Hartmann (1939, p. 25) pointed out that behavior originating at one point in development may serve an entirely different function later on (the concept of the “change of function”). Persistence of dependent behavior in adulthood cannot be treated as if it were a simple repetition of the individual’s early relationship with the mother. The same behavior in the adult is likely to be independent of the original drive and may serve quite different functions; in other words, it will have achieved “secondary autonomy” (Hartmann, 1950). The failure to recognize this change has been termed the “genetic fallacy” (Hartmann, 1955, p. 221). The critical adjustments to developmental theory were the twin concepts of primary and secondary autonomy in the ego. Whereas for Freud the ego depended on and only gradually differentiated from the id, for Hartmann and his colleagues (1946) the ego evolved out of an undifferentiated matrix from which the id and superego also emerged, and had autonomous functions that were independent of the id instincts, although these autonomous functions were still thought of as having their own evolutionary design and as being innately based. From the standpoint of aligning psychoanalytic theory with current neuroscience models, this was a critical move in that ego psychologists point to the innate (even modular) design of psychological capacities that involve subsystems of physical and social reality testing. In Hartmann’s (Hartmann et al., 1949) model, the ego will remain to some degree linked with the id because it uses energy from the drives. As aggressive impulses are more dangerous than libidinal ones, their neutralization in the course of development is vital. Without it, good object relations are inconceivable and the possibility of defense is forestalled, possibly leading to psychotic illness. Structural developmental theory is psychosocial in that Hartmann and his colleagues conceived of development as relying on an “average expectable environment” that affirms the importance of the actual parent. Development is seen as driven by a maturational pull and fixation in development that is as characteristic of ego as of id development. Individual differences in cognitive function that pervade personality may be understood as the consequence of developmental arrests in specific phases of ego development (Arlow, 1985; Brenner, 1982). Ego regressions, reactivation of developmentally earlier modes of functioning, may be maladaptive but can also serve as adaptive goals, such as artistic or scientific creativity (Blos, 1962; Kris, 1952).

Erik Erikson (1950) was primarily concerned with the interaction of social norms and biological drives in gener-

ating self and identity. His well-known description of eight developmental stages, later stages assuming the mastery of earlier ones, was based on biological events that disrupt the equilibrium between drives and social adjustment, cultural and family factors. He conceived of development as covering the entire life cycle. His stress on the basic need for a coherent self-concept only fulfilled in a supportive social milieu anticipated psychoanalytic ideas of the 1960s and 1970s (E. Jacobson, 1964; Kohut, 1971; Stechler & Kaplan, 1980). He extended Freud’s problematic erotogenic zone concept to a more subtle idea of “organ modes” (Erikson, 1959). The particular body part involved in a form of drive pleasure and drive expression also defined a mode of functioning. Thus, although the oral drive is initially expressed through the ingestion of milk, the mode of functioning that persists is one of taking in through eyes and ears. The concept of mode of functioning enabled Erikson to stay within the drive model but introduce enduring constructs such as identity, generativity, and basic trust.

Basic trust is defined as the capacity to receive and accept what is given. By emphasizing the interactive, psychosocial aspects of development, Erikson replaced excitement as the organizing construct of psychoanalytic developmental theory with a view that was inherently interpersonal and transactional in nature, organized around the child’s development of a sense of self. Westen (1998) considered investigations of Eriksonian concepts of identity (Marcia, 1994), intimacy (Orlofsky, 1993), and generativity (Bradley, 1997) to have been some of the most methodologically sound studies inspired by psychoanalytic theories of development. Erikson (1950) suggested that seemingly insignificant experiences would eventually combine, leading to

the firm establishment of enduring patterns for the balance of basic trust over basic mistrust. . . . [The] amount of trust derived from earliest infantile experience does not seem to depend on absolute quantities of food or demonstrations of love, but rather on the quality of the maternal relationship. (1959, p. 63)

This remarkable insight foreshadowed what we now understand about the creation of semantic memories (Schachter, 1996) and features in an important way in Bowlby’s (1980) concept of internal working models.

Spitz (1959) proposed that major shifts in psychological organization, marked by the emergence of new behaviors and new forms of affective expression (organizers), occur when functions are brought into new relation with one another and are linked into a coherent unit. The way these organizers herald dramatic changes in interpersonal

interactions was elaborated by Robert Emde (1980a, 1980b, 1980c). Spitz (1945, 1965) was one of the first to ascribe primary importance to the mother-infant interaction as a force in quickening the development of the child's innate abilities and to describe the role of self-regulatory processes such as the internal regulation of affect protecting the individual from psychological disturbance (Spitz, 1957).

Edith Jacobson (1964) creatively assumed that, because early drive states shifted continuously between the object and the self, a state of primitive fusion existed between early object and self-representations. Jacobson suggested that introjections and identificatory processes replaced the state of primitive fusion and that, through these, traits and actions of objects became internalized parts of self-images. Jacobson applied her developmental perspective to a wide variety of disorders, most particularly to depression, which she recognized as associated with the gap between self-representation and ego ideal.

Hans Loewald was probably the most influential reformist of the North American psychoanalytic tradition. Loewald (1971/1980c, 1973/1980b) proposed a developmental model that has at its center a motive force toward "integrative experience." Organizing activity defines the "basic way of functioning of the psyche." His fundamental assumption was that all mental activity is relational (both interactional and intersubjective; see Loewald, 1971/1980c, 1971/1980d). Internalization (learning) is the basic psychological process that propels development (Loewald, 1973/1980b). Loewald shifted emphasis from structures to processes, de-emphasizing metapsychology. He generated a subtle revision of the classical model that had internalization, understanding, and interpretation at its center (Cooper, 1988).

The Structural Model of Developmental Psychopathology

The structural model locates the origins of neurosis and psychosis at the point when an individual adult's urge to gratify drives reverts to a previously outgrown infantile mode of satisfaction. The symptoms that arise are compromises reflecting the many attempts of the ego to restore equilibrium between the opposing agencies of ego and superego and the unacceptable drive representations. As a result of psychological or organic problems, the ego itself may regress, with resultant pathology. In psychosis, there is a threat of total dissolution of the ego. If the ego resumes functioning characteristic of early childhood, it will come to be dominated by irrational, magical thoughts and uncontrolled impulses. Mental illness thus can be viewed as a

failure of the ego to maintain harmonious interaction between psychic agencies at age-appropriate levels.

A pathogenic sequence for neurotic problems may be delineated as follows: (1) frustration, (2) regression, (3) internal incompatibility, (4) signal anxiety, (5) defense by regression, (6) return of the repressed, and (7) compromise and symptom formation. Characteristic modes of compromise formation and specific developmental fixations result in particular neurotic reactions. The compromise in conversion hysteria reflects an oral or phallic fixation and is dramatically represented in a somatic form. In obsessional neurosis, it is assumed that the ego transforms anal sadistic and aggressive drive derivatives into secondary process thinking such as ruminations and obsessional doubts. The ego is developmentally unable to neutralize these drive derivatives. Aggression and anal concerns will remain apparent and result in massive anxieties (see, e.g., Fenichel, 1945; Glover, 1948). The process of neurotic compromise is seen as located in the thought processes themselves. On the other hand, the fear is externalized in the case of phobias, still possibly reflecting similar unconscious developmental concerns.

One way personality disorders were understood in structural theory was as character neuroses (Alexander, 1930). Here, despite dynamic similarity to neurosis, compromise formations are not split off from the ego and thus the symptoms are not experienced as ego alien or ego dystonic (see Waelder, 1960). The obsessional character neurosis shows better tolerance of the drive derivatives, although it otherwise reflects this compromise between id derivatives, ego, and superego. Another explanation is in terms of ego developmental arrest, deviations, or disharmonies that result in more severe personality disorders, such as Narcissistic Personality Disorder (see A. Freud, 1965). Faulty ego development is seen as at the root in the structural view (see J. Frank, 1956; Gitelson, 1955; Rangell, 1955). Patients may have a semblance of normality as some ego functions maintain their integrity despite impairment of important ego functions, such as reality testing, anxiety tolerance, and stable defenses.

Knight (1953, p. 6) proposed that Borderline Personality Disorder (BPD) resulted from trauma that impaired ego functions such as "integration, concept formation, judgment, realistic planning, and defending against eruption into conscious thinking of id impulses and their fantasy elaborations." In his developmental sequence of identity formation, Erikson (1956, 1959) described the syndrome of identity diffusion (a lack of temporal continuity of self-experience in social contexts). E. Jacobson (1964) described how, at times, individuals with BPD attach their mental and body self to external objects.

Both the problems and the strengths of the structural model are highlighted in psychoanalytic writings concerning Antisocial Personality Disorder (ASPD). The association between social deprivation and ASPD was initially explained as deprivation impeding the renunciation of the pleasure principle (Aichhorn, 1925) and pathological superego function (Fenichel, 1945; W. Reich, 1933). This was further specified as gaps in the superego (superego lacunae) that were believed to occur because of the parent's unconscious wish to act out forbidden impulses (Johnson & Szurek, 1952). Whereas a severe superego with a strong ego ideal was thought to generate depression, a menacing superego and a weak ego ideal led to ASPD. But many of these theoretical suggestions sound very like clinical descriptions. Thus, an absence of guilt concerning antisocial behavior is part of the definition of antisocial personality (Hare & Cox, 1987). Some more recent evidence, however, is in line with these classical works. Supporting Reich's and Fenichel's suggestions, it has been found that the presence of anxiety (autonomic reactivity) in antisocial youth reduces the risk of adult criminal behavior (Raine, Venables, & Williams, 1995). Recent behavior genetics research findings support the observations by Lampl-de-Groot (1949) that depression and antisocial behavior show closeness and opposition. Depressive symptoms and antisocial behavior share common genetic influences and may co-occur because of common genetic roots that increase vulnerability to both these types of problems (O'Connor, McGuire, Reiss, & Hetherington, 1998).

Structural theorists see psychotic symptoms as regressions to normal but very early functioning. Severe ego impairments are seen as being caused by some basic fault in laying down psychic structure during infancy. In Greenacre's (1953, p. 10) view, "The matrix of these severe disturbances lay in the disturbances in that period at the very dawn of the ego, roughly around 6 months and a little later." However, modern developmental observations are inconsistent with the notion of a "normal" confusional state between self and object (Gergely, 1992, 2000). It has been shown that from birth, infants are able to accurately identify their mother and even to imitate facial gestures (Meltzoff & Moore, 1997).

Evaluation of the Structural Model

The structural model, once coterminous with psychoanalysis in the United States, is now all but extinct. Change in the notion of the id undoubtedly foreshadowed its demise. Contemporary structural theorists (see, e.g., Loewald, 1971/

1980c, 1971/1980d, 1978, 1978/1980a) typically have reinterpreted Freud's concept from a container of all biologically based intense physical desires to an organization related to reality and human figures. The original model was criticized in the 1970s and 1980s for its quasi-physiological character (Compton, 1981; G. S. Klein, 1976a; Rosenblatt & Thickstun, 1977), its homophobic outlook (Schafer, 1974), and the primacy it gave to sexuality in explanations of psychopathology (M. Klein, 1980; Peterfreund, 1978).

The major criticisms of drive theory as being reductionist, biologically naïve, and overinfluenced by the naïve physiology of nineteenth-century Central Europe (Rosenblatt & Thickstun, 1977) have been tempered by more recent reviews of drive theory. Repeated exposure to various drugs of dependence results in sensitization of a specific neural pathway in the brain (the dopaminergic ventral tegmental pathway) that forms the substrate for intense motivations (Berridge & Robinson, 1995). Howard Shevrin (1997) has linked the "wanting system," identified as abnormally sensitized (oversensitive) in drug-dependent individuals, with the ego psychological notion of psychic energy and drives. Further evidence comes from Panksepp's (1998) description of the anatomically linked (Shevrin, 2001) "SEEKING system" (also described as "psychic energisation"; Panksepp, p. 145), which prompts an animal to explore very energetically and self-stimulate endlessly to achieve the state of expectance without needing to fulfill the drive. There is a subjective state of pure anticipation embodied in this system, with no apparent object. A state of wanting exists that later, through processing in more advanced brain systems, acquires an object and mental representation. Finally, the neuropsychological work of Solms (1997a, 2000), linked with recent radiological and pharmacological findings, implies that the brain stem mechanisms that are known to control the REM state can generate dreams only through the mediation of a second, probably dopaminergic, forebrain mechanism. Solms suggests that the dopaminergic ventral tegmental pathways are the initiators of dreaming and that the pathway from the ventral tegmental area connecting the amygdala, septal area, cingulate gyrus, and frontal cortex is the final common path to dreaming. The system that is sensitized in drug addiction is identified by Solms as the neural system forming the substrate for the motivational impetus for dreaming. The neural systems that activate dreaming and that activate craving are thus identical. Each and every dream, however, starts in the neural structure that most closely fits Freud's concept of instinctual drive states: the ventral tegmental area.

SPECIFIC STRUCTURAL DEVELOPMENTAL PERSPECTIVES

Three psychoanalysts, two from the United Kingdom and one from the United States, have made critical contributions to psychoanalytic developmental theory. All three have started from the basis of the structural approach, but all three ended up modifying the structural tradition in various ways.

Anna Freud and Developmental Psychopathology

Anna Freud (1965) was the first psychoanalyst to adopt a coherent developmental perspective on psychopathology. However, her view of development was classically Freudian, in that she saw developmental progress as a child coming to terms with developmentally expectable conflicts, where the child has to find a compromise among diverse wishes, needs, perceptions, physical and social realities, and object relations. Anna Freud took her father's theory forward by identifying ways that the parent contributed to the construction of the child's ego or superego, but she always subordinated this process to the overriding principle of the search for drive satisfaction.

She provided a comprehensive developmental theory using the metaphor of developmental lines to stress the continuity and cumulative character of child development (A. Freud, 1962, 1963). In her initial presentation of this view, six developmental lines were considered, of which the developmental line from dependency to emotional self-reliance and adult relationships was considered the most fundamental. Other lines included the movement from egocentrism to social partnerships, from sucking to rational eating, and from irresponsibility to responsibility in body management. Anna Freud (1974) added other lines in later papers, for example, from animate to inanimate objects and from irresponsibility to guilt.

The lines emphasize observable behavior at the same time as specifying the internal psychic development necessary for the achievement of each step along each line. The lines were not designed to provide a new metapsychology but to reduce the complexity of understanding development through identifying specific sequences of progress (Neubauer, 1984).

Pathology is assessed in terms of large discrepancies among the lines and notable lags with respect to normal progress along each line. Developmental lines have etiological significance, with unevenness of development being regarded as a risk factor for psychiatric disturbance. Arrest or regression in a particular developmental line can be the formulation for a child's problem (A. Freud, 1965). Clinically,

in addressing a child's disturbance, the psychoanalytic clinician should offer "developmental help" to the child, restoring him or her to "the path of normal development" as well as focusing on the determinants of the child's symptoms (Fonagy, Miller, Edgumbe, Target, & Kennedy, 1993; A. Freud, 1970b, 1983; H. Kennedy & Moran, 1991).

Developmental lines were used to describe a range of pathologies that emerged between neurotic and psychotic states, preneurotic nonconflictual disorders. An analogy may be made between this group of disorders and personality disorder in adults. Anna Freud (1965, pp. 148–154) identified disturbances of narcissism, object relatedness, and the absence of control over aggressive or self-destructive tendencies alongside a range of deficiencies of development. This prescient developmental perspective, however, was never properly reconciled with structural theory.

Anna Freud (1970a) also suggested that there was a developmental aspect to the emergence of anxiety problems in childhood. Both the content and the quality of fears changed with the developmental phase. Earlier fears, with less advanced ego development, were more intense, more likely to be rooted in fear of loss of the object. Later-emerging fears, such as fears of operations, robbers, and ghosts, are more likely to be rooted in Oedipal anxieties. Anxiety can turn into guilt with full development of the superego. There is, however, little evidence to support the notion that affects are more primitive at early stages of development (see also Emde, 1980b, 1980c; Stern, 1985).

A further developmental distinction was made by Anna Freud between "objective anxiety" (such as fear of any aspect of the external world, including the parents' real reactions) and fear of the internal world (impulses, wishes, and feelings; Sandler & Freud, 1985). She noted in the work of the Hampstead war nurseries (A. Freud & Burlingham, 1944) that children and adults showed different reactions to external threat. Children were less likely to be traumatized by being bombed if during this experience they were with their mother and if the mother remained calm. An extremely carefully conducted study of children's reactions to Scud missile attacks in Israel provides more recent support for this finding (Laor et al., 1996). The study showed that if the child's mother showed significant reactive symptoms, the child was far more likely also to show prolonged symptoms of anxiety following the attack.

Anna Freud's concept of ego restriction was substantially elaborated in her later work on developmental deficits. Severe personality disorders were considered as characterized by developmental deviations or disharmonies, such as deficits in reality testing, development of

defenses, anxiety tolerance, superego strength, and so on. Inadequate maternal response to an infant's instinctual needs causes dangers and external conflict (Yorke, Wiseberg, & Freeman, 1989). This disharmony between need and environment will be most acute when the developing structure is not yet capable of sustaining the pressures resulting from the consequent internal and external stresses.

Anna Freud should perhaps be described as a modern structural theorist. Her model is fundamentally developmental. The individual is seen as capable of moving back along developmental lines if that is needed to deal with some current, potentially overwhelming challenge. The individual can then move forward again. Here there is no equation of behavior and pathology; a given behavior may not be a true symptom, but a temporary blip. The notions of mobility of function and the meaning of behavior are key assumptions of broader developmental approaches to psychopathology (Cicchetti & Cohen, 1995; Garmezy & Masten, 1994).

Anna Freud and Dorothy Burlingham showed, for psychoanalysts, an unusual commitment to the observational method. Many findings from Anna Freud's observational work during the war in the Hampstead nurseries (1941 to 1945) are consistent with contemporary developmental research. This includes the development of an attachment relationship during the first 6 months of life, the rise in ambivalence to the caregiver between 6 and 12 months, the impact of trauma and its psychic impact (Posttraumatic Stress Disorder), the parent's use of withdrawal of affection to socialize the child, and the early sociability of the infant. She also initiated fascinating research follow-up studies (Bennett & Hellman, 1951; Burlingham, 1952; Burlingham & Barron, 1963; Hellman, 1962; H. E. Kennedy, 1950).

However, Anna Freud's insistence on the literal use of her father's structural model of drives limits the usefulness of her model. She regarded drive fixation, the balance between the three structures of the mind, id, ego, and superego and so on as the most scientific aspects of her father's contribution and was loath to abandon them. But her revision of the structural model is hidden behind her modesty about her innovation. Masten and Curtis (2000) draw attention to the two historically rich traditions of the study of the development of competence and psychopathology, both of which are present in the history of psychiatry and psychoanalysis but are not commonly integrated. Development of competence has remained the domain of developmental psychology, and disturbance and dysfunction have been in the realm of child and adult psychiatry. Perhaps Anna Freud's corpus is a notable exception to this tendency to separate competence from pathology (Masten & Coatsworth, 1995).

Margaret Mahler and the Pathology of Separation-Individuation Processes

Margaret Mahler, with Rene Spitz, was the first thoroughgoing developmentalist of the North American tradition. She elaborated a psychoanalytic model of development based on observations of 6-month to 3-year-old children. Mahler's (Mahler & Furer, 1968, Mahler et al., 1975) developmental model sees object relations and the self as elaborations of instinctual vicissitudes. Her focus is on the move from the unity of "I" and "not-I" to eventual separation and individuation. She holds that the "biological birth of the human infant and the psychological birth of the individual are not coincident in time" (Mahler et al., 1975, p. 3). Separation, in Mahler's model, refers to the child's emergence from a symbiotic fusion with the mother, whereas "individuation consists of those achievements marking the child's assumption of his own individual characteristics" (p. 4).

Mahler's developmental model is as follows:

1. The first weeks of life are considered a stage of "normal Autism." The infant is assumed to be surrounded by an autistic shell that keeps external stimuli out.
2. The symbiotic phase, beginning in the 2nd and 3rd months, is a state of undifferentiated fusion with the mother with a common delusional somatopsychic boundary. This phase is regarded as the basic source of benevolent feelings about the self and toward the object and is the reference for checking back perceptually and emotionally in later phases.
3. Separation-individuation begins with the subphase of differentiation (of the body image; Mahler & Furer, 1968; Mahler et al., 1975).
4. From 9 months to about 15 to 18 months is the second subphase of separation-individuation: practicing. This is thought to be characterized by a sense of omnipotence derived from sharing mother's magical powers, practicing locomotion, and returning for emotional refueling.
5. The rapprochement subphase is dated as the second half of the 2nd year, when the toddler becomes aware of separateness and there is an increased need to be with the mother. Mahler's term for this combination of clinging while pushing or darting away is "ambitendency" (Mahler et al., 1975, p. 95). The mother's handling of this is regarded as crucial.
6. The fourth subphase of separation-individuation is the consolidation of individuality that begins with the 3rd year of life. Its goal is the firm establishment of the cog-

nitive-symbolic inner representation of the object and the achievement of individuality.

Mahler (1974) described her work as enabling clinicians treating adults to make more accurate reconstructions of the preverbal period, thereby making patients more accessible to psychotherapeutic interventions. Her work has been extensively used, particularly by North American clinicians working with personality disordered adults (see Kramer & Akhtar, 1988; Pine, 1985; Settlege, 1977). The clinical conclusions to emerge can be summarized as follows:

1. Narcissistic Personality Disorder may be linked to the inadequate soothing ministrations of the mother during the symbiotic phase and inadequate refueling during separation-individuation. Therefore, the omnipotence of the practicing subphase is never completely renounced. Findings from research on parent-child relationships in Japan and in the United States, however, suggest that prolonging the symbiotic union between mother and infant does not undermine the individual's capacity to achieve autonomy (Rothbaum, Pott, Azuma, Miyake, & Weisz, 2000).
2. Individuals with BPD experience residues of the rapprochement subphase conflicts with persistent longings for and dread of fusion with the other. It is thought to be associated with either aggression or withdrawal on the part of the mother during the rapprochement subphase (Mahler & Kaplan, 1977; Masterson, 1985). Masterson suggests that the object, who is desperate to feel needed, rewards the toddler for demanding and clinging behavior. There is limited evidence available to support the suggestion that BPD is a transgenerational disorder. A positive history of psychopathology is more commonly found in one or both biological parents than would be expected by chance (Paris, 2000; Shachnow et al., 1997). The finding of low parental care combined with high overprotection has been identified in questionnaire-based investigations (Goldberg, Mann, Wise, & Segall, 1985; Torgersen & Alnaes, 1992) and retrospective interview-based studies (Paris & Frank, 1989; Zweig-Frank & Paris, 1991). A recent study of mothers with BPD found that they were more intrusively insensitive toward their 2-month-old infants than were mothers without psychiatric disorder (Crandell, Patrick, & Hobson, 2003).
3. Severe deprivation may prevent the normal psychological birth of the infant from normal Autism and generate a character disorder that resembles schizoid personality, with poverty of affection and relationships (Burland, 1986).

Although Mahler's model has been highly influential, systematic experimental research with infants casts serious doubt on dual notions of normal Autism and self-object merger (Gergely, 2000). Further, the infant does not seem to be a concrete experience of the physical world, as Mahler assumed. Rather, infants are acutely sensitive to abstract, amodal properties and cross-modal invariances. Intensified sucking action translates readily into observed movements of a mobile in the infant's mind (Stern, 1993). However, Mahler's developmental framework may well be appropriate for the truly psychological world of the human infant. The infant is aware of self and object as separate in the physical (bodily) domain but assumes that psychological states extend beyond physical boundaries (Fonagy, Moran, & Target, 1993). The 9-month-old infant conceives of the object as rational behaving in accordance with goals, and initially this early teleological understanding of behavior seems not to be differentially linked to animate rather than inanimate objects (Csibra, Gergely, Brockbank, Biro, & Koos, 1999; Gergely, Nadasdy, Csibra, & Biro, 1995). Thus, a symbiotic intersubjective unity may indeed characterize infancy and even early childhood, but solely at the level of mental representations of mental states.

It is now clear that Mahler's assumptions about severe forms of childhood psychosis, such as infantile Autism and childhood Schizophrenia, poorly fit her developmental model and seem unlikely to be explained by the notion of a developmental fixation in the symbiotic phase. While the most promising explanation for Schizophrenia remains a neurodevelopmental one, with numerous indications of neurological, cognitive, and behavioral dysfunctions long before the onset of the disorder, evidence points to the last months of gestation rather than the first months of life as a critical period for the vulnerability to potential causes of Schizophrenia (Marenco & Weinberger, 2000). Evidence in favor of postnatal pathological processes is meager. Similarly, the early emergence of symptoms characterizing Autism is generally accepted, but the resistance to social interaction is seen as an extreme form of a constitutional bias toward processing information from the physical rather than the interpersonal world (Baron-Cohen, 2000). Thus, although recent research confirms Mahler's theory that these serious disorders are evident from the first months of life, her implication that they are caused by the social events that take place in this period has not been substantiated.

Mahler's original contributions to the understanding of BPD have been most lasting. Her view of these patients as fixated in a rapprochement, wishing to cling but fearing the loss of their fragile sense of self, wishing to be separate but

also fearing to move away from the parental figure, has been crucial to both clinical intervention and theoretical understanding. However, her theory is less helpful in understanding the high prevalence of childhood maltreatment in these patients' lives, particularly sexual abuse, for which there is now overwhelming and high-quality evidence (e.g., K. C. Jacobson & Rowe, 1999).

Joseph Sandler and the Bridging of Structural and Object Relations Theory

Joseph Sandler, a student of Anna Freud, was instrumental in the modernization of psychoanalysis, preparing its integration with the developmental sciences. As many of his ideas have been seamlessly integrated into modern core theory, we will only briefly enumerate his central contributions and touch on the relationship with related ideas reviewed elsewhere.

1. Sandler introduced the frame of reference of the representational world, an approach very similar to the schema theory that has come to dominate social and cognitive-behavioral psychology (see Sandler, 1960b; Sandler & Rosenblatt, 1962).
2. Sandler placed feeling states rather than psychic energy at the center of the psychoanalytic theory of motivation (Joffe & Sandler, 1967, p. 64). He introduced the revolutionary concept of background of safety, within which the aim of the ego is to maximize safety or security rather than to avoid anxiety (Sandler, 1960a). He did not get rid of drives, but he explained their influence on behavior through the impact they had on feelings (Sandler, 1972).
3. Sandler (1976) described how patients tend to create relationships to actualize unconscious fantasies by casting themselves and their therapists in specific relationship patterns, and by extension offered an entirely new theory of internal object representations (Sandler & Sandler, 1978). He showed how wishful fantasies are represented as interactions between self and object, the basic aim being to bring about a good emotional state while distancing a bad one.
4. Sandler differentiated the deeply unconscious hypothetical structures assumed by classical psychoanalysis to develop early in life and that have no chance of directly emerging into consciousness (the past unconscious) from the present unconscious, which also worked as Freud described (irrational, only partly observing the reality principle but principally concerned with current rather

than past experience; Sandler & Sandler, 1984). The second system, the present unconscious, consists of here-and-now adaptations to conflicts and anxieties triggered in the first system, which was a genuine continuation of the past into the present (Sandler & Sandler, 1987).

5. It is difficult to overestimate the clinical significance of these and other advances (Fonagy & Cooper, 1999). But Sandler's direct contributions to clinical theory were more limited. In one significant contribution, he linked pleasure in experiencing particular styles of perceptual and cognitive functions with specific forms of pathology (Sandler & Joffe, 1965b). For example, obsessiveness, painful though it may be, is also linked to pleasure in childhood. The developmental model of depression that Sandler proposed also made use of the representational world construct (Joffe & Sandler, 1965; Sandler & Joffe, 1965a, 1965b). Loss of the ideal states of young childhood that are omnipotent or unrealistic but failing to adopt new ones that fit with reality generates the depressive response.
6. In further clinical formulations, Sandler (1987) explained the concept of projective identification without making the extravagant assumptions, which many Kleinian authors made (see later discussion). The "other" can come to enact the patient's fantasy because the patient attempts to modify or control the behavior of the other so that it conforms to his or her distorted representation of the other. The patient's representation of the other comes to be distorted through the mechanism of projection, experiencing the other as owning unwanted aspects of the self-representation. This model is helpful in explaining therapeutic phenomena such as countertransference and phenomena identified by emotional developmental research, such as the transgenerational transmission of patterns of mother-infant interaction (Fraiberg, Adelson, & Shapiro, 1975; Sandler, 1994).

Sandler was one of the most creative figures enabling psychoanalysis to be a psychology of feelings, internal representations, and adaptations closely tied to the clinical origins of psychoanalysis. He found common ground between American ego psychology and British object relations theory. His contribution was built on the potential for integration created by the collapse of associationist psychology and the emergence of a cognitive science. A number of individuals commencing their journey from cognitive science research (see, e.g., the outstanding contributions of Bucci, 1997; Erdelyi, 1985; Foulkes, 1978; Stern, 1985; Westen, 1991) attempted to cross this bridge and were at least partially successful in doing so because Sandler created the

bridgehead on the other side. Although his theories were, and are, extensively used, those who use his ideas often are unaware of doing so. Thus, there is no psychoanalytic school that bears his name. He advanced thinking by clarifying a range of psychoanalytic concepts but was unable to excite his colleagues with the novelty of his contributions.

A PARADIGM SHIFT TO OBJECT RELATIONS

Many psychoanalysts were dissatisfied with the mechanistic, somewhat reductionist character of structural theory. From Freud's earliest writings relationships had played a key part in his theorization. Most importantly he viewed the relationship between mother and infant as determining expectations about subsequent relationships, although these speculations were mostly translated into the language of drives and cathexes. Increasingly, clinicians confronted with conscious and unconscious concerns about relationships which dominated the narratives of their clients shifted the center of gravity of theorization from concerns about psychic energy and mental structures to attempting to understand the internal representations associated with social relationships, particularly those between the infant and the objects of his affection, the mother and father.

Overview of Object Relations Theory

Object relations theories in psychoanalysis are "concerned with exploring the relationship between real, external people and the internal images and residues of relations with them and the significance of these residues for psychic functioning" (Greenberg & Mitchell, 1983, p. 14). This definition is not satisfactory, as it would include many psychoanalysts who would not consider themselves object relations theorists (e.g., Edith Jacobson, Rene Spitz). It would be more accurate to argue that object relations theories are those psychoanalytic approaches that seek an understanding of psychopathology in terms of mental representations of dyadic self and object relationships that are rooted in past relationships, at first dyadic, later triadic, and still later multiple relationship representations. The increased interest in relationships is part of an underlying refocusing away from psychoanalysis as the study of intrapsychic conflict toward an experientially based perspective emphasizing the individual's experience of being with others and with the therapist during analytic work. This approach, which became dominant during the 1980s, increasingly emphasizes phenomenological constructs such as a person's experience of self, his or her experience of psychic reality

(i.e., subjectivity). As people express themselves mostly in terms of relationships, the move toward a broadly relational psychology may simply be the consequence of clinicians exploring the patient's narrative from the perspective of his or her subjectivity.

Object relations theories assume that the child's mind is shaped by early experiences with the caretaker. Object relations become increasingly complex with development. It is further assumed that early patterns of object relations are repeated. Thus, they are in some sense fixed throughout life. Disturbances in these relations explain pathology, and the patients' reactions to the therapist provide a window for examining healthy and pathological aspects of early relationships. Some theories, but not all, assume an "autonomous relationship drive" that forcibly brings the individual into contact with the caregiver (e.g., attachment theory). Other object relations theories derive relationships from drive theory (e.g., Winnicott), and yet others are able to derive a theory of drives from object relations (e.g., Kernberg). A helpful distinction between these theories was offered by Friedman (1988), who distinguished between hard and soft object relations theories. Hard theories, in which he includes the theories of Melanie Klein, Fairbairn, and Kernberg, see much hate, anger, and destruction and dwell on obstacles, illness, and confrontation, whereas soft object relations theorists (Balint, Winnicott, and Kohut) deal with love, innocence, growth needs, fulfillment, and progressive unfolding.

By the mid-1980s, object relations theory, in one of its many incarnations (see later discussion), was the most widely accepted psychoanalytic model around the world. Home-grown versions of the theory (Kohut, Kernberg) and British imports (Klein, Winnicott) replaced ego psychology in the United States; the British version of the theory came to hegemonize much of Europe, and both North American and British theories in modified forms could be found in the vibrant Latin American psychoanalytic movement (e.g., Etchegoyen, 1991). However, by no means all psychoanalysts have accepted the shift of the basic psychoanalytic model from the classical Freudian structural model to object relations theory. In North America, there are a number of psychoanalysts who remain fully committed to modifications of the structural approach as proposed, for example, by Brenner (1982, 1987, 1994). Other influential writers, such as Harold Blum (1986, 1994), Vann Spruiell (1988), Len Shengold (1989), and the Tysons (Tyson & Tyson, 1990), have managed to retain a broadly ego psychological perspective while selectively adopting certain object relations ideas. None of these writers, however, has wished to advance a psychoanalytic model that may serve as an alter-

native to object relations theory. Only writers in the interpersonalist tradition have aspired to do this.¹

The Klein-Bion Model

Melanie Klein and Wilfred Bion are perhaps the two psychoanalysts least concerned with a developmental framework for psychological disorder. Yet their formulations concerning the infant's (or, more realistically, the child's) mental life are important and interesting because they highlight negative aspects of emotional development frequently ignored by nonpsychoanalytic clinicians. Further, as the genetic predisposition to most mental disorders is becoming increasingly well established, psychological models of the mediation of genetic vulnerability are of great interest. M. Klein's (1930, 1935/1984a, 1959/1984d) work combines the structural model with an interpersonal, object relations model of development, with a powerful emphasis on constitutional vulnerability rather than caregiver behavior as the prime determinant of developmental pathways. Klein's papers on the depressive position (1935/1984a, 1940/1984c), her paper on the paranoid-schizoid position (1946), and her book *Envy and Gratitude* (1957/1984b) established her as the leader of an original psychoanalytic tradition. There are several excellent introductions to the work of Klein; these include Segal (1974), Caper (1988), and Hinshelwood (1989).

Fantasies about an Infant's Mental World

The Klein-Bion model of development is highly speculative, all of it retrospectively constructed from observations

of adult patients, children with serious mental disorder, and infants without epistemological restrictions on the attribution of complex internal states to them. Notwithstanding this unpropitious start, the model has been remarkably influential in that it provided a psychological account of puzzling self-destructive and relatively immutable behaviors. Here we summarize key points of this highly complex and elaborate theory.

1. Klein uncritically accepted and built on Freud's speculation of a self-destructive drive (the death instinct; S. Freud, 1920/1955).
2. Klein postulated two modes of mental function, one dominated by the separation of the good and the bad, the idealized and the persecutory (the paranoid-schizoid position), and the other a more mature, simultaneous balanced recognition of the bad in the good and one's role in unrealistically and self-servingly distorting the world into idealized and denigrated components (the depressive position). M. Klein's (1935/1984a) metaphor for these two states of mind was the perception of the mother as separately idealized and persecuting in the paranoid-schizoid state and perceived as a whole person who accounts for both good and bad experiences in the depressive position.
3. It is assumed that discovering one's hostility to a loved object and accepting responsibility for creating an image of her as bad and yet identical with the image of her as perfect is linked to pain and anxiety and is resisted. This is what Klein calls "depressive anxiety," as distinct from the "persecutory anxieties" of the earlier paranoid-schizoid position. Bion (1957) was the first to point out that the depressive position is never permanently achieved. In fact, the very term "position" suggests a permanence that this state of mind rarely has. It is now accepted that the mind cycles between the two (paranoid-schizoid and depressive), as the achievement of depression creates anxiety which can only be handled in the paranoid-schizoid state (by more primitive defenses, such as splitting).
4. The concept of "projective identification" is central to this model (M. Klein, 1946). Whereas in the classical theory of projection, impulses and wishes are experienced as part of the object rather than the self, and identification implies attributing qualities perceived in the object to the self, projective identification involves externalizing "segments of the ego" and attempting to gain control over these unwanted possessions via often highly

¹ The sole geographic exception to the domination of object relations theory is the group of French-speaking countries, particularly France and French Canada. Here a specific version of Freudian theory has remained dominant throughout the last decades of the twentieth century. A review of French psychoanalytic ideas would require a separate book of its own (such as the Lebovici & Widlöcher, 1980, volume summarizing postwar French psychoanalytic thinking). One justification for the limited coverage of the French school of psychoanalysis in the present volume is the limited interest of French theoreticians in a developmental perspective (A. Green, 2000), which is the organizing theme of the present chapter. Green regards the developmental frame of reference as part of psychology rather than psychoanalysis. Green's concept of time as nonlinear (polysynchronous) is inconsistent with the fundamental assumptions of developmental psychopathology: the accumulation of risks for development from experience and privileging of early experience as a primary response to later encounters.

manipulative behavior toward the object (i.e., making the other identify with the projections).

5. Projective identification is not a defense, but an interpersonal process where the self gets rid of feelings by evoking the feelings in another self (Bion, 1962a).
6. The origins of this process are to be found in infancy, when the baby projects “unprocessed elements” (beta elements) into another human mind (the container) that can accept them and transform them into meanings (alpha function), which the baby can reinternalize, creating a representation of these experiences (Bion, 1959).
7. Working with children, Klein (1932) was impressed by their ruthless, sadistic fantasies, which she felt were not a reaction to frustration but represented innate aggression. A malign form of this is primitive envy, which is hatred directed at the good but also at times inaccessible object (M. Klein, 1957/1984b). The child resents the inevitable limitations of maternal care, cannot tolerate the mother’s control over it, and would prefer to destroy it rather than experience the frustration.
8. While paying lip service to the parent’s capacity to mitigate the influence of the child’s constitutional tendencies, Klein (1952, 1959/1984d) was convinced that the internal experience of others and self were innate. Post-Kleinian authors argued that although primary destructiveness was constitutional, it could with difficulty be mitigated by or aggravated by environmental influences (e.g., Segal, 1981). It has to be said that recent evidence suggests that physical aggression and destructiveness are indeed particularly marked in the early years in most children and naturally decline in most children over the course of the first decade, with violent children manifesting an absence of this expectable taming rather than an emergence of aggression *de novo* in response to environmental impingement (Shaw, Gilliom, Ingoldsby, & Nagin, 2002; Tremblay, 2000; Tremblay, Japel, & Pehrsson, 1999).

The Kleinian Model of Mental Disorder

By and large, the Kleinian model of psychopathology assumes that mental disorder constitutes a persistence of the primitive mental states discussed earlier. Mental disorder indicates the predominance of the paranoid-schizoid position, whereas mental health reflects the relative stability of the depressive framework. The cause of pathology is primarily constitutional (overwhelming envy) and may be aggravated by deficiencies in the mother’s capacity for

reverie (Bion, 1967), which is similar to Winnicott’s (1962b) concept of primary maternal preoccupation (see later discussion). Persecutory anxiety threatens the ego, and anxiety and experience of fragmentation, annihilation, and a loss of a capacity for integration might be observed—a constellation characteristic of severe personality disorders. In psychotic states, annihilatory/persecutory anxieties are intense, and the object with whom the patient attempts to projectively identify is reintrojected, that is, experienced as entering the ego, creating a delusion of the mind or the body being under external control (M. Klein, 1946).

Neurotic problems are seen as consequences of unresolved, depressive anxiety. For example, depression arises because the experience of loss reminds individuals of the damage they felt they caused to the good object (M. Klein, 1940/1984c). Chronic depression arises when the person cannot escape the fear of injuring the loved object and therefore has to repress all aggressiveness, generating a relentless self-persecution. Narcissistic character structure is considered a defense against envy and dependence. The narcissist’s relationship with others is highly destructive. The narcissist makes ruthless use of others and denies his or her need of them (Rosenfeld, 1987). There are two kinds of narcissism: thin-skinned (where the person seeks constant reassurance) and thick-skinned (the hostile, superior, isolationist posture; Rosenfeld, 1971). Character disorders in general, such as narcissism, are thought to be underpinned by relatively stable constructions of impulses, anxieties, and defenses, which allow the individual to create an internal state felt to be protective from the chaos of earlier developmental stages at the cost of developmental progress to more advanced modes of psychic functioning (Steiner, 1993). The system is rigid but unstable. Defenses may shift, but progress is more apparent than real. Bion (1962a) suggests that an early disabling of the psychic processes needed for understanding cognitive and affective aspects of interpersonal relationships is responsible for this.

Evaluating the Klein-Bion Model

Early critics of Kleinian formulations focused on the centrality of really early higher-order cognitive and perceptual capacities (see King & Steiner, 1991, for a definitive account of the “controversial discussions” that took place in the British Psycho-Analytical Society in 1944). These critiques contrasted Kleinian claims with “commonsense” views of what babies can think; that is, Kleinian theory was tested against folk psychology or

observation, rather than empirical research (see, e.g., Glover, 1945; Yorke, 1971).²

The human infant does indeed have remarkably abstract and complex cognitive capacities (see, e.g., Meltzoff, 1990), but there is no evidence to support Klein's implicit claim that the infant relates to the object as a psychological entity. Melanie Klein consistently held that the baby had awareness of the minds of others, which we now know the child is most unlikely to have until at least the 2nd year (Baron-Cohen, Tager-Flusberg, & Cohen, 2000). Laboratory-based research reveals infants' representations as far less concrete and relatively abstract and amodal (see Bower, 1974), which does not support Kleinian and post-Kleinian assumptions about "infantile part-object" representations such as breasts and penises. Nevertheless, the emergent research-based model of the human mind is increasingly recognizing the importance of innate concepts, wired in and selected by evolution, and in this context (e.g., Buss, 1995), it has to be said that some of Melanie Klein's ideas no longer seem as far-fetched as they did at first. None of this is proof of her ideas, nor is it likely that her fantasies about the infant's mind state will ever be confirmed, but the idea that gene-driven affective reorganization of the brain in infancy influences the later functioning of the brain cannot be dismissed as implausible given the directions in which developmental science is progressing.

Klein's ideas have provoked considerable controversy and ill feeling. There are concerns about attributing adult psychological capacities to infants, considered earlier, but the question also arises as to why Klein dates pathology to such early stages (Bibring, 1947). The answer might be that the mental states of infancy are extremely hard to observe: The postulation of crucial pathogenic processes in infancy is extremely unlikely to be disproven. Psychoanalytic infant observation (Bick, 1964) also permits widely differing interpretations. However, evidence is accumulating that most of the important mental disorders of adulthood are indeed foreshadowed in infancy (e.g., Marengo & Weinberger, 2000). Further, early brain development is increasingly seen as pivotal in the evolution of psychological disturbance (Schore, 2003).

The work of Kleinian writers represents a major advance in clarifying the relationship between emotional de-

velopment and psychological functioning. Many of their ideas have enriched the field of psychoanalytic theory and clinical practice well beyond their own school. Many of these ideas remain to be operationalized for further study, but models such as Bion's (1962a, 1962b) container/contained have lessened the divide between the understanding of cognitive development and that of emotional disorder. This is essential to further advances in the field of developmental psychopathology.

The Independent School of British Psychoanalysis

The appropriately named independent tradition is the work of a number of individual analysts, has no single leader or theorist, and therefore lacks the theoretical coherence of the tighter groups. Fairbairn (1954, 1963) and Guntrip (1961, 1969, 1975, 1978) were the theory builders, with major contributions from Winnicott (1953, 1958), Balint (1959, 1968), Klauber (1966, 1987), Khan (1963, 1974), and Bollas (1987, 1989). They all explicitly refrained from establishing schools of followers. There are some excellent summaries of their work (see, e.g., Hughes, 1989; Kohon, 1986; Rayner, 1991; Sutherland, 1980).

The Developmental Model of the British School

The developmental assumptions of the independent school, with special reference to the work of Donald Winnicott, may be summarized as follows:

1. There is a primary drive for creating object relationships (Fairbairn, 1952), with a less widely held further assumption of a primary human desire to feel loved (Balint, 1968).
2. Insufficient intimacy with the primary object will give rise to a "splitting" in the self, and it is this persistence of incompatible ideas and lack of integration between them rather than intersystemic conflict and repression that is at the root of psychological disorder (Fairbairn, 1952). The intimacy and integration is assured by the holding environment, where the caregiver, in a state of primary maternal preoccupation, holds the infant to give him the illusion that she can accurately respond to his gestures because his wish created her and she is part of him (Winnicott, 1962b, 1965a). Holding is based on comprehension, "a holding in mind of the infant's mental state." Holding protects the infant from unbearable mental experience, overwhelming archaic anxiety, while he or she moves from an unintegrated to an integrated state (Winnicott, 1962a).

²For example, projection in the paranoid-schizoid position assumes a differentiated sense of self and other, because without this, it would be impossible to displace the source of bad feelings from the self onto another object. It also implies that the baby can blame his or her own feelings on the attributed attitude of the other, that is, make a causal attribution.

3. Holding is communicated by mirroring that is never perfect but is “good enough” and permits repair (Winnicott, 1967). The lack of perfection allows for failure and frustration, which facilitate the break away from infantile omnipotence and give an opportunity to the mother to repair the inevitable hurt by permitting regression to complete fusion.
4. Winnicott (1953) introduced the idea of transitional phenomena in a study of how the infant uses the mother to achieve independent functioning. A corner of blanket may help to soothe the infant as it is grasped when the infant fantasizes about breast-feeding. It is associated with conjuring the mother (and the breast) in her absence. The physical object (blanket) is both the mother (the “not-me” aspect) and the infant (the “me” aspect). Transitional objects are to be found in the space between the self and external reality in which (according to Winnicott) symbolization occurs, meaningful, affectionate, sharing yet separate companionship and love grow, where play and illusion are maintained in the spontaneous, creative activities of healthy people (Winnicott, 1971).
5. The emergence of the self is through an integration of spontaneous, creative interactions with the mother that are nonintrusive and that facilitate the illusion that the object is a product of the baby’s creative gestures and therefore controlled and controllable.
6. If the mother cannot comprehend the infant, he or she will be forced into compliance, and a “false (compliant) self” to protect the true self will develop (Winnicott, 1965a).
7. Winnicott distinguishes between privation (never had maternal care) and deprivation (sufficient awareness of care for the self to develop and experience withdrawal of care). Antisocial Personality Disorder is associated with the latter pattern and assumes the presence of a self (Winnicott, 1956).
8. It is the mother’s lack of love and lack of recognition of the child’s love rather than primary destructiveness that leads the child to believe that his or her hate has destroyed the object (Fairbairn, 1952; Padel, 1972).

British Independent Contributions to Developmental Psychopathology

Fairbairn’s (1944) key contribution was the proposition that an early trauma of great severity is stored in memories that are “frozen” or dissociated from a person’s central ego or functional self. This is particularly relevant to Narcissistic and Borderline Personality Disorders, but the

notion of multiple self-representations is of more general importance. Fairbairn (1952) sees the schizoid reaction of withdrawal from and primitive defense against the trauma of not being intimately known or loved as fundamental to all pathology. Winnicott (1965b) and Fairbairn (1954) associated Schizophrenia with total privation, that is, the complete absence of good enough mothering. It is assumed that the experience of privation makes the infant view his or her love as bad and destructive. This in turn makes the infant withdraw from emotional contact with the outer world and ultimately creates a highly disturbed sense of external reality. Severe personality disorder may be seen as the result of having had a good enough mother who had been lost, and thus feeling forever deprived. Schizoid personality (Fairbairn, 1940, 1952) arises out of the baby’s feeling that love for the mother is destructive of her and therefore has to be inhibited along with all intimacy. The ego is split, and neither other nor self is perceived as a whole person. Both hide their love and protect themselves from the love of others. Winnicott (1965a) adds that this includes a falseness in self-presentation which becomes truly maladaptive only when called on to function in the context of an intimate interpersonal relationship. Guntrip (1969) added that the rejection from a hostile object leads to a hunger for objects that are feared. Borderline patients are considered by Winnicott (1960) to share defenses with psychotic patients, which is consistent with many modern epidemiological perspectives (Gunderson, 2001). Winnicott notes that these patients have no sense of others, including the therapist, as having lives of their own and respond with threats of intense anger if their sense of omnipotence is threatened.

These observations have been confirmed empirically in studies showing that borderline patients have a specific deficit in mental state awareness in the context of attachment relationships (Fonagy et al., 1996). This phenomenon is explained by Modell (1963, 1968) as individuals with BPD relating to people as if they were transitional objects (inanimate objects from which to obtain comfort in mother’s absence). This transitional relatedness makes them use other people as if they were inanimate to serve a self-regulating, soothing function; used, as a toddler uses a teddy bear, in primitive, demanding, and tenacious ways. Searles (1986) and Giovacchini (1987) believe that this shows how patients with BPD may have been treated by their parents—as transitional objects. Narcissistic individuals are thought to have been poorly mirrored; they fall back on a compensatory self-structure to bypass having to rely on inadequate caregivers. This is, however, illusory self-sufficiency and unreal autonomy (Modell, 1975, 1984).

Evaluating the British Independents

The British independents' views have only partially stood the test of time. The general approach to development, the description of infants as biologically prepared to attend to environmental events that respond to them, has been very well supported by infant research (Meltzoff & Moore, 1998; Watson, 2001). It seems highly plausible that there is a biological path to social interaction, in the course of which the infant can be reflected as a mental entity. For example, research on affective interactions between infant and mother support the notion of a dual unit of infant and mother, where the mother and infant mutually create the infant's moods (Jaffe, Beebe, Feldstein, Crown, & Jasnow, 2001; Tronick, 2001). Winnicott's views on the importance of sensitive maternal care are broadly supported by developmental research, although there is general dissatisfaction with the fuzziness of the concept of maternal sensitivity (De Wolff & van IJzendoorn, 1997). Longitudinal research with Romanian infants adopted late strongly supports Fairbairn's and Winnicott's assumptions concerning the long-term impact of privation (Carlson et al., 1995; Chisholm, Carter, Ames, & Morison, 1995; O'Connor, Bredenkamp, Rutter, & the English and Romanian Adoptees Study Team, 1999; O'Connor, Rutter, & Kreppner, 2000). Increasingly, there is evidence of neurophysiological and even neuroanatomical deficit associated with such privation (Chugani et al., 2001; Gunnar, Morison, Chisholm, & Schuder, 2001; Kreppner, O'Connor, & Rutter, 2001).

Research does not, however, support Winnicott's exclusive concern with the infant-mother relationship. Although there is good evidence that low levels of parental warmth and support, as well as parental rejection and hostility and family conflict are associated with a range of psychological problems in children (Ge, Conger, & Simmons, 1996; Sheeber, Hops, Alpert, Davies, & Andrews, 1997), the evidence does not support the privileging of the mother-child relationship (see, e.g., McCauley, Pavidis, & Kendall, 2000, for research on childhood depression). Winnicott's assumption that the relationship between infant and mother provides the basis for all serious mental disorder also flies in the face of accumulating evidence for the importance of genetic factors (Rutter, Silberg, O'Connor, & Simonoff, 1999a, 1999b).

The data from behavior genetics studies should be considered in relation to all psychoanalytic theories (as well as other theories focused on early socialization); we consider these data here because Winnicott's description of the potential toxicities in the infant's psychosocial environment

was highly influential. For example, two large-scale, high-quality, community-based studies, the Virginia Twin Study (Eaves et al., 1997; Hewitt et al., 1997) and the Nonshared Environment and Adolescent Development Project (NEAD; Reiss et al., 1995), have confirmed that most types of childhood psychopathology have quite substantial genetic components. The nonshared environment appears to be the bulk of the environmental component; shared environment, an instance of which would be parental sensitivity, accounts for almost no variance (Plomin, 1994). Modern reviews of the controversy (see particularly Rutter, 2000) offer quite balanced evaluations. For example, it is now clear that claims about the absence of shared environmental effects in behavior genetics studies have been exaggerated because they are estimated simply in terms of how alike or not siblings are. The importance of the influence of factors such as maternal warmth cannot be estimated in this way because the influence impacts different members of the family in different ways: It will appear to be a non-shared environmental influence, whereas it is actually shared. Further, most studies of the influence of early environment on development are based on twin and adoptive studies that sample environments of lower than average risk (Stoolmiller, 1999). There are further technical complications. For example, many studies drawing inferences about causation have conflated nonshared environmental variance with error variance, and other studies have assumed that identical and fraternal twins have "equal environments." It is quite likely that the critics have exaggerated their claims; nevertheless, they have provided a valid challenge to psychosocial researchers (Rutter, 1999).

To summarize, evidence suggests that Winnicott overstated the case for environmental influences on normal and pathological development. Whereas psychoanalysts prior to Winnicott and the British independents have been inclined to environmentalism and preferred nurture to nature explanations of pathology, the Freudian heritage was one of great respect for constitutional factors and the role of genetics, for example, in symptom choice and vulnerability to environmental stress. Although never totally rejecting the role of constitutional factors, in psychosis for example, Winnicott's theory emphasized the exclusive role of the early environment to a degree that has turned out to be clearly incompatible with the behavior genetics data.

The major weakness of Winnicott's theory, which actually runs across the entire British object relations tradition, is what may be called a naïve reconstruction of infancy in the adult mind. Although infant research confirms some speculation and informal observation, the developmental

argument of a linear evolution from infancy to adulthood cannot be sustained. Human development is far too complex for infantile experiences to have direct links to adult pathology. In fact, to the extent that such research is available, longitudinal studies of infancy suggest that personality organization is subject to reorganization throughout development based on significant positive and negative influences (e.g., Emde & Spicer, 2000).

Winnicott's view influenced psychoanalysis in a subtle and profound way. For example, Kohut's advances of psychoanalytic theory, which are covered in the next section, are almost entirely anticipated by Winnicott's work, although this is rarely acknowledged. Winnicott's influence has unhappily been epistemological as well as theoretical. His style of writing is highly evocative, and his clinical examples are rich as well as persuasive. His writing is untroubled by considerations of parsimony, the need for unambiguous language or supportive evidence. In Winnicott's hands this approach has been highly creative; in the hands of his followers, evocative language can often disguise convoluted speculation and uninspired content.

The Self Psychological Approach

Self-psychology theory emerged in the late 1960s and early 1970s and became one of the dominant psychoanalytic approaches in the United States, although it never properly penetrated European psychoanalytic thinking (Mollon, 2001). It emerged from the thinking of Heinz Kohut (1971, 1977; Kohut & Wolf, 1978).

Developmental Theory

Kohut was particularly concerned with the difficulties of individuals with Narcissistic Personality Disorder. Self-psychology came to be generalized to other problems of mental disorder and together with a specific therapeutic approach, foregrounding empathy. Although self-psychology is not a coherent theory, Kohut's own thinking having shifted considerably, it is possible to identify a number of key developmental assumptions in this body of work:

1. Kohut's formulation is that narcissistic development proceeds along a path of its own and that parents serve as selfobjects. A selfobject is defined as a person in the environment who performs particular functions for the self; these functions evoke the experience of selfhood (Wolf, 1988a). The mother who treats the child as though the child has a self initiates the process of self

formation. The functions of the selfobject are to integrate the child's affects through differentiating between affects, assisting in tolerating affects, and assisting in thinking about affects (Stolorow, 1997; Stolorow & Atwood, 1991).

2. To begin with, empathic responses from the mirroring selfobject (assumed to be the mother) allow the unfolding of exhibitionism and grandiosity. This aspect of the self emerges as a defense against the awareness of vulnerability and relies on confirmation through an object who mirrors the child's need for admiration and approval. This enables the child to build an idealized image of the parent with whom he or she wishes to merge.
3. Frustration, when phase-appropriate and not too intense, permits a gradual modulation of infantile omnipotence through "a transmuting internalization" of this mirroring function. Transmuting internalization of the selfobject leads gradually to consolidation of the nuclear self (Kohut & Wolf, 1978, pp. 83, 416).
4. The idealization of selfobjects, also through internalization, leads to the development of ideals. The internalizing of the mirroring function and idealized selfobject leads to the emergence of a "bipolar self," with its ambitions and ideals and the natural talents available to it.
5. In Kohut's later writings (1977, 1984), the self was regarded as a superordinate structure incorporating drives and defenses. The main developmental achievement for any individual is the attainment of a cohesive self.
6. It is the "enfeebled self" that turns defensively toward pleasure aims (drives), which are the breakdown products of disappointments to the self, usually involving failures in emotional attunement of the selfobject. Anxiety is primarily the self's experience of a defect or lack of continuity.

The Self Psychological Model of Developmental Psychopathology

The self psychological model of psychopathology is essentially a deficiency theory. A deficiency of facilitating experiences is assumed to lead to a primary psychic deficit: an inadequately developed self. In the self psychological model, fear of losing the sense of who one is underlies all pathology. Secondary conflicts that we observe can occur only because of structural weaknesses in the self. Diagnostic distinctions can be made in terms of the characteristics of the self: (1) Psychosis precludes a cohesive sense of self; (2) personality disordered patients have an enfeebled self vulnerable to temporary fragmentation; and (3) neurotic

pathology is thought to be associated with the robustness of self structure. Narcissistic personality is a developmental arrest at the stage of the grandiose exhibitionistic self, which fails to be neutralized by the parent's age-specific mirroring responses. Parental failure causes an arrest in the movement from the grandiose exhibitionistic self to realistic ambition, or the idealization of the parental imago to ego ideal. Repression of the grandiose self is associated with low self-esteem, vague depression, and lack of initiative (Rosenfeld's thin-skinned narcissism). When splitting dominates, the grandiose self manifests as boastfulness, arrogance, and a dismissing attitude out of touch with reality (Rosenfeld's thick-skinned narcissism). Low self-esteem, hypersensitivity to criticism, and the need to continue to be mirrored characterize both.

Neurotic anxieties are also considered a consequence of deficient selfobject function. Thus, agoraphobia may be a consequence of the maternal selfobject's failure that led to a deficit in self-soothing function, that turns anxiety into disintegration anxiety (Kohut, 1984). Violent behavior is triggered by a threat to the self, experienced as a sense of shame, which generates an overwhelming need to inflict injury on the shaming person and repair the narcissistic injury (Gilligan, 1997). Borderline Personality Disorder results from an inability to hold on to selfobjects psychologically who might be soothing to the self. The result is inner emptiness and a failure of self-organization that causes annihilatory panic when relationships are threatened (G. Adler, 1985). Drug addiction is thought to fill a missing gap in the psyche. When the selfobject fails to perform a tension-regulating function and there is traumatic disappointment in the idealized object, the drug is used to fill the gap that the object left behind (Kohut, 1977).

Evaluating Self-Psychology

Because of the fundamental similarities between Kohut's and Winnicott's approaches, much of the evidence bearing on Winnicott's views is also pertinent to self-psychology. Thus, for example, the notion of an innate contingency detection module (Gergely & Watson, 1999) that functions to detect probabilistic relationships between the actions of the infant and environmental events is naturally consistent with both Winnicott's and the self psychological models of development. The hypothesis that at around 3 months of age the infant's orientation shifts from searching for perfect contingencies that help it identify its body to high, but imperfect, degrees of contingency that pinpoint aspects of the social world, links closely to the work of Stolorow and colleagues (Stolorow, Brandschaft, & Atwood, 1987; Watson, 1994) concerning emotional development. Self psycholo-

gists have also felt supported by the identification of so-called mirroring cells in the primate brain (Gallese, 2000, 2001; Gallese & Umiltà, in press). These are cells that appear to be activated when the rhesus monkey identifies a movement analogous to its own in the world. (It should be borne in mind that monkeys do not recognize themselves in the mirror; the suggestion here is for a predisposition to identifying environmental events pertaining to the self.) Although *prima facie* this is consistent with a developmental emphasis on mirroring, it is somewhat far-fetched to consider it a direct confirmation of self psychological ideas. There is evidence that mothers who speak to their infant as if the baby had a self enhance the likelihood of secure attachment (Oppenheim & Koren-Karie, 2002), even when mother-infant interaction is observed at 6 months and attachment at 12 months (Meins, Ferryhough, Fradley, & Tuckey, 2001). There is also a large body of evidence that supports the central role of self-esteem in the generation of psychological disturbance. For example, it is clear that life events that trigger feelings of humiliation and entrapment are particularly powerful in triggering episodes of depression (Brown, Harris, & Hepworth, 1995). Further, individuals with early adverse experiences that are likely to have undermined their self-esteem are most likely to respond with depression to negative life events (Brown, 1998).

There has been appropriate criticism of Kohut's model as parent-blaming. Tyson and Tyson (1990) take issue with his emphasis on pathogenic parents, neglecting the infant's constitution and capacity to modify his or her own environment. At the root of his formulation of narcissistic personality and behavior disorders is the idea that these result from faulty selfobject responses to the narcissistic needs of the growing child between the phase of primary narcissism and the Oedipal phase. This is a naïve environmentalist position, from the perspective of modern developmental psychopathology. Correlations between characteristics of early parenting and later child behavior can be reinterpreted given that any association may be attributable to the 50% of genetic overlap between a parent and a biological child. This has been termed "passive genotype-environment correlation." In a landmark investigation of genetic and environmental influences on adolescent development, Reiss and colleagues (Reiss, Neiderhiser, Hetherington, & Plomin, 2000) found that of 52 statistically significant associations between family relationship (e.g., parental warmth, sibling relationships) and measures of adjustment (e.g., depression and antisocial behavior), 44 showed genetic influences that accounted for more than half of the common variance. In almost half of the 52, little association between family relations and adolescent functioning remained once genetic

influence was taken into consideration. Further, there is the so-called child-to-parent effect, where aspects of the family environment are shaped by the child's genetically rooted characteristics (best shown in adoption studies; e.g., Deater-Deckard, Fulker, & Plomin, 1999).

Self-psychology represents a genuinely radical revision of psychoanalytic ideas. It is not surprising, perhaps, that it has been subjected to considerable criticism, particularly from those who see it as having been overextended from an explanation of narcissistic disturbances to all forms of psychological disorder (Schwartz, 1978). Kohut consistently failed to acknowledge the link between his ideas and other theories, including structural theory (Rothstein, 1980), the work of Alexander and French (1946), and the work of Loewald (1960), and there is scant reference to the work of Winnicott. In an apparently helpful clarification, Wolf (1988b) pointed out that selfobject needs are concrete only in infancy; in later development, they can be increasingly abstract, with symbols or ideas serving selfobject functions. Anything that makes a person feel good may be considered to have a selfobject function, and the only way we know if an activity or person has selfobject function is through observing its effects on well-being. Used this broadly, the concept has no explanatory power.

The Structural Object Relations Perspective

Otto Kernberg, who trained as a Kleinian analyst, has mainly worked in the environment of ego psychology and yet achieved a remarkable level of integration between these two, quite possibly epistemologically inconsistent (Greenberg & Mitchell, 1983), developmental frameworks (see Kernberg, 1975, 1980a, 1980b, 1984, 1992). Kernberg does not fully adopt the Kleinian model of development, although he makes good use of Kleinian concepts (such as the model of early object relations and superego formation, aggression, envy, splitting, projective identification) in understanding severe psychopathology. Ultimately, his model is a creative combination of the ideas of the modernizers of structural theory (Jacobson, Sandler, Loewald, Mahler) and the Klein-Bion model. This may account for Kernberg's being the most cited psychoanalyst alive and one of the most influential in the history of the field. In summarizing his views, we focus attention on points of difference between his perspective and those of relational and structural theorists.

The Structural Object Relations Developmental Model

Similarly to Sandler, Kernberg considers affects to be the primary motivational system. The dyadic representation of

interaction between self and object, colored by particular affects, constitutes the basic building block of psychic structure (Kernberg, 1982). Drives are hypothetical constructs manifested in mental representations of the self and object linked by some dominant affect state. Self-object-affect triads (object relations units) are stored in affective memory and evolve into drives in the context of the mother-infant relationship, as was originally suggested by Loewald (1971/1980c). Drives remain motivators of behavior and, unlike in the Kleinian or British object relations approaches, are not replaced by object relations structures. The major psychic structures (id, ego, and superego) are integrations of internalizations of object representations in self-object relationships under various emotional states. Thus, a superego may be harsh because of a prevailing affect of anger and criticism.

There are three processes of internalization: (1) introjection, where entire interactions of self and other are internalized in their affective context; (2) identifications that recognize the variety of role dimensions that exist in interaction with others; and (3) ego identity that denotes the overall organization of introjections and identifications (Kernberg, 1976). Kernberg outlines a developmental sequence borrowed from Jacobson and Mahler with a far less specific timetable. In essence, in early stages, good and bad object images are split by the ego to protect good images from the destructive power of bad ones. In the 3rd year of life, the polarized good and bad representations are thought to become gradually more integrated so that total object and self-representations are formed. Ego weakness following the failure to achieve the ego integration associated with integrating good and bad parts of self and object representations creates vulnerability to character pathology, retaining splitting as opposed to repression as the principal mechanism of defense. After age 3, Kernberg's theory follows the structural model of development.

The Structural Object Relations Theory of Psychopathology

Kernberg offers a comprehensive reconsideration of psychological disorders, but his model of neurotic pathology does not differ fundamentally from the structural perspective, although it is influenced by Klein, Fairbairn, and Mahler. Where he differs from these pioneers is in his focus on the current state of the patient's thinking rather than attempting to identify where currently dominant pathogenic conflicts and structural organizations originated. For example, he is not concerned with distinguishing Oedipal from pre-Oedipal pathology but simply asserts that all levels of disturbance are more complex if

linked with severe personality disturbance. The treatment literature that shows outcomes from both pharmacologic and psychotherapy of Axis I disorders to be systematically poorer when accompanied by Axis II diagnoses is consistent with this point of view (J. H. Reich & Vasile, 1993; Shea et al., 1990). However, unlike other psychoanalysts, Kernberg is serious in his consideration of psychiatric diagnostic categories as predictors of treatment response. For example, he does not consider severe character problems to be appropriately treated in psychoanalysis. He recommends twice-weekly expressive psychotherapy as the treatment of choice.

We focus on Kernberg's approach to personality disorders (where his contribution is most clearly valued). Even neurotic pathology entails self-object dyadic configurations dating to developmentally earlier stages than the integrated units of self or object and reflecting either a defensive or an impulsive aspect of early psychic conflict. An individual is considered susceptible to anxiety when configurations of self- and object representation are poorly differentiated and highly affectively charged. For example, a representation of the self as weak and vulnerable may be coupled with an object representation of ruthless domination with a violent affective tone (Kernberg, 1984). At mild levels of character pathology, there is some splitting as well as repression. Therefore, inhibitions are considered to be weak and impulsivity is marked. There will be rapid reversals so that self-representation and projected object representations can switch. Patients who believe they are the victims of criticism (from the therapist) can suddenly turn into the vicious unreasonable critic. Note that not only is the ego poorly organized and unstable, but the superego is harsh and sadistic (Kernberg, 1988). At severe levels of character pathology, primitive dissociation or splitting of internalized object relations is marked (Kernberg, 1984). There is a consequent lack of integration of self- and object representations, and integrated representations of object relations are absent. There is no tolerance for ambivalence, which is replaced by a defensive disintegration of self and objects due to libidinally or aggressively invested part-object relations. The individual insists on consistently constructing either idealized or persecutory self and object relations, making relationships with such individuals confused or chaotic (Kernberg, 1984).

Narcissistic personality functioning is rooted in a lack of realistic self-concept and a self-image split into grandiose and devaluing aspects that alternate. The overriding need to gain external support for the grandiose self undermines the capacity for mutual relationships. The admired other stands

for qualities that are felt to be lacking in the self and must therefore be constantly controlled, and there is no real empathy. In malignant narcissism, the idealized object images that are normally integrated into the superego are integrated into the grandiose self; such a person may feel empowered to perform severely antisocial acts and take sadistic pleasure in victories over others (Kernberg, 1975). Although narcissistic disorders may sometimes serve to protect an individual against an underlying borderline personality organization, the latter is considered a separate nosological entity characterized by (1) ego weakness (poor affect tolerance, impulse control, and sublimatory capacity), (2) primitive defenses including splitting, (3) identity diffusion, (4) intact reality testing but a propensity to shift toward dreamlike (primary process) thinking, and (5) pathological internalized object relationships. The root cause of borderline states is the intensity of destructive and aggressive impulses and the relative weakness of ego structures available to handle them.
